PLATES IN VOLUME II, 1919.

			Facing Page
Plate	I.	Spindle-Like Formations in the Inflamed Uveal Tissue of Sympathetic Ophthalmitis, Colors	1
Plate	II.	Section of Tumor Showing Connective Tissue Masses and Fat Cells in Stark's Case of Tumor of the Cornea	6
Plate	III.	Section of Tumor of Cornea (Stark's Case) Showing Papillae on Part of the Surface	8
Plate	IV.	Fundus by Red Free Light, Colors (O. Y. B.)	1
Plate	V.	Map Showing Relative Frequency of Trachoma in Counties of Illinois	84
Plate	VI.	Intraocular Hemorrhage in Bright's Disease	177
Plate	VII.	Recurring Growth Extending on the Cornea in Vernal Conjunctivitis	233
Plate	VIII.	Congenital Eye Conditions, Colors	377
Plate	IX.	Cases of Congenital Ptosis	408
Plate	X.	Detachment of Retina in Toxemia of Pregnancy, Colors	473
Plate	XI.	Granuloma of Cornea, Colors	510
Plate	XII.	Choroideremia, Colors	543
Plate	XIII.	Blood Staining of Cornea, Colors	633
Plate	XIV.	Dimitry's Substitute for Enucleation	654
Plate	XV.	Dimitry's Substitute for Enucleation	654
Plate	XVI.	Tuberculosis of the Retinal Vessels, Colors	715
Plate	XVII.	Tuberculosis of Retinal Vessels	718
Plate	XVIII.	Macular Hole in the Retina, Colors	779
Plate	XIX.	Hole at the Macula	792

INDEX OF NAMES

Abadie, C. 375.
Abbondy, M. 840.

SUBJECT INDEX

A number in **heavy face type** gives the page of an original article, including translations, editorials, and correspondence. Numbers in (brackets) refer to abstracts, including those given in society proceedings. Other numbers indicate incidental mention of a subject, as in the titles given in Ophthalmic Literature. The index for the Digest of the Literature is separate from this and will be found at the end of the book. Names are indexed separately.

Abderhalden's experiments, 471.
Abducens nerve in man, 171.
  paralysis, **197**, 709, **710**, **773**.
Aberration, 371.
Abiotrophy, retinal, (431), 840.
Abscess, brain with paralysis, 306.
  of tear sac, 174.
  orbital, (154), (352), 551, 713.
Absorption of cataract, 550, **682**.
Abstracts, 59, 158, 217, 356, 451, 537, 616.
Accommodation, 76, 627, (751), 838, 839, **858**, **859**, (880).
  in lensless eye, **858**, (882).
  loss of from poppy seeds, 627.
  paralysis of, **609**, 709, 773, 839, 858.
  spasm of, **202**.
Acidity and cataract, 550.
Acne rosacea, (205), 372, 468.
Acraflavin, **892**.
Actinomycosis, (57).
Acuity of vision, (147), 230, (293), 371, 626, 627, 709, 712, (750), 838, (874).
Adaptation, **13**, 18, 78, 308, 629, 712, (758), 896.
Adaptometer, 305, 626, 773.
Addison's disease, **77**.
Adduction and retraction of globe, (203).
Adenoids, 372, 714, 896.
Adenoma, 551.
Adiposis dolorosa, 309.
Adrenalin, 895.
Advancement, **606**, 709.
Age of parent and eye color of infant, 552.
Air Service Medical, (457), (755).
Albinism, 388.
Albumin and cataract, 896.
Albuminuric retinitis, 78, **473**, (537), 551, 711, 775.
Alexia, 470, 629.
Amaurosis, see Blindness.
Amaurotic family idiocy, 308, 373, 550.
Amblyopia ex anopsia, 838.
  hysteric, 174, 311, 376, 777.
  See also Toxic Amblyopia.
Amblyopes, reading glasses for, 305.
American Academy of Opthalmology and Oto-Laryngology, (367).

Wood, C. A. Eye, Ear, Nose and Throat, 835.
Bowman lecture, (434).
Braille writing, 232.
Bright's disease, and ocular hemorrhage, **177.**
Buphthalmos, 172, 230, (288), 372, 466, (528), (695).

Calves, hereditary cataract in, **681.**
Canalicotomy, abuse of in epiphora, **542.**
Capsular extraction, 173, 468, 550, **866.**
Capsule, rupture of, (348).
Capsulotomy in senile cataract, **854.**
Carcinoma choroid, 310, 898.
conjunctiva, 310.
epibulbar, 80, 310.
limbus, 471.
orbit, (58), 375.
Carotid and pituitary body, (612).
aneurysm of, 309, 310.
Caruncle, trachomatous changes in, **243.**
Cataract, (344), (345), (348), 840, **893,** 896.
absorption of, 550, **682.**
and delirium, 173.
and glaucoma, **601.**
and uveitis, **108.**
artificial ripening, 175.
arrested development, 78.
causes of, 629, 775, 896.
congenital, 78, 775, **681.**
cortical, 173.
diabetic, 469, 896.
family, 173.
genesis of, 78.
gray, 472.
juvenile, 468, 469, 629.
lamellar, 550, 775.
localization of, 709.
Morgagnian, **743.**
radium treatment of, (614), 840.
radiating, 468.
refraction in, **420.**
secondary, 469, 775.
senile, 78, 171, (345), **423,** 629, (749), 896.
traumatic, 629, **682,** 711, 775.
unilateral, **426.**
zonular, 78, 308.
Cataract extraction, (66), 231, 308, 373, **423,** 268, 469, 550, 629, 711, 775, **854,** 896.
intracapsular, 173, **866.**
statistics of, 629.
suppuration after, 896.
suture of cornea in, 550, 841.
Cellulitis, 374.
Cerebral blinding from injury, 776.
tumor, 174, 309, 374, 713, 897.
Cerebrospinal fever, 472.
fluid, 552.
meningitis, (43), 311, 842.
Cervical sympathetic, 231.
paralysis of, 176, **254.**
Charcoal, 467.
Charcot-Leyden crystals, 3.
Chauffage, (698), 839.
Chemotherapy, 710.
Chicago Ophthalmological Society, 207, 351, 445, 529, 825.
Chinese and trachoma, **500.**
keratoconjunctivitis in, 467.
Chinolin, 549.
Chloroform iodid, 709.
Choked disc, 79, 231, 309, 469, 629, 711, 841.
after extirpation of thyroid, 629.
Cholesteremia, 472, 840.
Chorea, 471.
Choroid anomalies of, 387, 468, **553, 618.**
gumma of, 307.
inflammation of, 628.
melanoma of, (613).
muscles in, 173.
senile changes in, 175.
tubercle of, 307.
veins of, 308.
Choroideremia, congenital, **553, 618.**
Choroiditis, 373, 710.
disseminated, (350), 468, (527), 710.
guttate, 386, 387.
macular, (528).
Choroidoretinitis, (438), 629, 712.
Ciliary body circulation of, (610).
incision in glaucoma,
nerves, 173.
proliferation from, 307.
sarcoma of, (445).
Cilium in anterior chamber, 839.
Cinchonism, 631.
Cinemas, 895.
Cinematoscopy, 776.
Circulation and tension, 629.
Civil practice, 176.
Clinics, for school children, 778.
of St. Louis Medical Society, (370).
Cocain, 171, (293), 373, **428,** 626.
in keratitis, 774.
injections in glaucoma, 775.
Cohn theory of myopia, 627.
Cold and corneal changes, 896.
Collargol, 626.
College of Physicians of Philadelphia, 74, 284, 289, 348, 609, 694.
Colloidal manganese, 467, 549.
Colloids and color of eyes, 896.
Collyria, 76, 171.
Coloboma, choroid, 468.
Fuchs', 384, 386.
iris, 468.
lens, 385, 468, 840, (871).
lid, 841.
optic nerve, 469, 896.
retinal, 711.
Colorado Ophthalmological Society, 153, 214, 343, 442, 526.

Color blindness, 14, 176, 551, 630.
discrimination, 712, 841.
perimeter, 712.
primer (Ostwald's), 79.
scheme (Kemp-Prosser), 376.
sense, 79, 712.
symbolism, 776.
tests, 79.
vision, 14, 78, 79, 231, 374, 410, 551, 712, 776, 841.
Colored rings and diffraction, **185.**
Comfort test, 371.
Comparative ophthalmology, 376, 631, 714, 778, 898.
Compensation in injury, 312, 376, 472, 632, **813,** (825).
Compresses homatropin, 626.
Computation of injury, **813,** 825.
Concussion, (60), 231, (284), **314,** 552.
and contusion in warfare, **314.**
Congenital eye conditions, **377.**
Congress, Oxford, 176.
world of ophthalmology, **221, 889.**
Conical cornea, see Keratoconus.
Conjunctiva, 77, 230, 306, 372, 467, 628, 774, 838, 895.
cauterization of, 774.
detaching of bulbar, **183.**
eruptions on, 467.
examination of, 77.
histology of, 628.
pemphigus of, (289), 467.
sensitiveness of, (66).
shrinking of, 372.
streptotrichosis of, 839, 895.
tissues and cells of, 774
tubercle of, **679.**
ulcer of, 372.
xerosis of, 549, 838.
Conjunctival flap, 174, 311, 466.
inflammation, (necrotic), 467.
scars, (290).
tuberculosis, 172, 230, (343), (361), 467, 628, 710, 774, 778.
Conjunctivitis, 306, 389, 467, **525,** 710, 774, 838, 839, 896.
and anaphylaxis, **486.**
hemorrhagic, 172, 306, 710.
catarrhal, 306.
chronic, 172, 230, 628.
contagious, 172, 710.
diphtheritic, 172.
dysentery, 172.
epidemic, 172, 710.
exuberant pericorneal, **234.**
follicular, 896.
gonorrheal, 172, 230, 372, 594, 710, 774, 839.
hebronemic, 172.
Koch-Weeks, 306, 774.
meningococcic, 839.
necrotic, 467.
Parinaud's, 77, 549, 896.
petrificans, 306.
phlyctenular, 172, 230, 372, 390, 527, 710.
pneumococcic, 709.
provoked, 549, 628, 774.
pseudomenbranous, 839.
scar tissue in, **81.**
treatment of, **180.**
typhoid, 306.
typhus, 549.
ulcerative, 372.
vernal, 172, 230, **234, 241,** 372, (443), 549, 774, 839.
Conjunctivoplasty, 713.
Consanguinity, 311.
Conservation of vision, 170, 176, 552, 631, 714, 773, 778, **836,** 898.
Constantinople, eye diseases in, 77.
Contusion of globe, **314.**
Convergence, 838.
after excitement, 709.
insufficiency, 230, **338,** 467.
Copremia and retinal hemorrhage, 551.
Cornea, 77, 172, 230, 306, 372, 467, 550, 628, 710, 774, 839, 896.
blood staining of, **307, 633.**
blue, 372, 839.
composition of, 839.
conical, see Keratoconus.
curve, 173.
cyst, 774.
fatty degeneration of, 77, (291), 467.
granuloma of, **510.**
herpes of, 77, 468.
leucoma of, 467.
nerves of, 307, 468.
ring infiltration in, 77, 372, 550.
sensitiveness of, (66), 896.
Corneal activity, 172.
anesthesia, 550.
changes, (56), 372, 896.
dystrophy, 372.
inflammation, 230, 710.
microscope, 76, 895.
nebula, 550.
necrosis, 467, 839.
opacity, 77, (154), 172, 306, 307, 467, 468, 628, 710.
pigmentation, 231, (341), 467.
reflex, 77, 467.
staphyloma, 628, 710.
tattooing, 77, 372.
ulcer, 77, **87,** (160), 172, 230, 307, 372, 467, (698), 710, 774, (819), 839.
Corneo-scleral trephining, 231, 468, 632, 771, 775.
Corrections, 767.
Correspondence, 367, 702, 836.
Couching, 307.
infection of vitreous, 307.
Council, general medical, and ophthalmologists, 714.
Craniospinal form and allignment, **493.**
Credé method, 372.
Crookes' lenses, 232, 312, 472.
Cross cylinders, 895.
Crossed eyes, see Strabismus.
Cryptophthalmos, 174.
Crysolgan, 777.
Crystalline lens, 78, 173, 231, 308, 373, 468, 469, 550, 629, 711, 775, 840, 896.
calcareous (445).
couching of, 307.
diffraction in **185.**
discission of, 373, 550, 629, 775.
disintegration of, 78.

dislocation of, 173, 308, 373, (445), 711, 840, (871).
embryonic, 550.
heterogeneity of, 775.
opacity of, see Cataract.
power to neutralize alkalies, 775.
resorption of, 468.
shadow formation in, 775.
subluxation of, 468, 775.
Vossius ring on, 775.
Culdesac, reconstruction of, 549.

SPINDLE LIKE FORMATIONS FOUND IN UVEAL TISSUE IN SYMPATHETIC OPHTHALMITIS, SHOWN PRINCIPALLY EMBEDDED IN FUCHSINOPHILE CELLS. (ICHIKAWA.)

AMERICAN JOURNAL OF OPHTHALMOLOGY

Vol II. JANUARY, 1919 No. 1

SPINDLE LIKE FORMATIONS IN THE INFLAMED UVEAL TISSUE OF SYMPATHETIC OPHTHALMITIS.

PROF. K. ICHIKAWA, M. D.

KIOTO, JAPAN.

These observations, reported from the University Eye Clinic of Kioto, call attention to a class of bodies that have hitherto received little attention from histologists, but are probably crystals and of considerable importance. With one colored plate. Translated from the German by H. W. Aufmwasser, M. D.

Of late I have been able to demonstrate in bacteriologic investigations of sections of eyes enucleated for sympathetic ophthalmitis, a spindle-shaped formation in the inflammatory uveal tissues. As this remarkable occurrence has not been previously observed by any one, I wish to report about it in the following:

Siegrist,[1] Manolescu,[2] Quint,[3] Calhoun,[4] Chaillous,[5] Browning,[6] and others have noted the favorable effect of salvarsan in sympathetic ophthalmitis. This therapeutic experience has brought authors to believe that the exciting cause of this illness may be in close connection with the exciting cause of syphilis. This seemed to be more probable, since Gradle[7] could prove in three cases of perforating injuries of the eyes, the presence of a spirillum.

I have, therefore, in my investigations made it my task to prove the correctness of this conception. The eyeballs which I had for my experiments were seven in number. For the identification of the spirochetes we used the method of Levaditi. Among these seven eyeballs, six were already embedded in celloidin, so that these had to be freed from celloidin for the Levaditi treatment. They were all sympathizing eyes and have shown the typical picture of sympathetic ophthalmitis.

The result of this examination was, however, wholly negative, altho I examined the sections very carefully.

Since my first examination was without result, I tried then to find any bacteria in the sections of the sympathizing ophthalmitis.

That the histologic picture of this affection is very similar to that of tuberculosis, is sufficiently known. No one has succeeded so far in proving the presence of tubercle bacilli in the inflamed tissue of sympathetic ophthalmia. Neither have the numerous tests by implantation on animals susceptible to tuberculosis furnished a positive proof. The search for bacteria of other nature was also negative.

As matters stand, the finding of bacteria in the tissue of sympathetic ophthalmitis is therefore an exceedingly difficult problem. In spite of all this, the fact that no one used the method of Ohtori[8] of staining, for the bacteriologic investigation of sympathetic ophthalmia, caused me to stain these sections by this method.

I have stained by this method numerous sections which had been kept in the clinic for a long time. In the beginning the results were entirely negative. Occasionally, however, I have found in one of the sections, which was treated for a short time with acid, a highly remarkable fact, a fact which no one had so far observed. That is

the occurrence of peculiarly formed fuchsinophile structures in the inflamed uveal tissue. I wish, therefore, to report more minutely about these structures.

Morphology.—It concerns a spindle-like formation whose size fluctuated. In length it measured 6.64μ to 2.82μ, in thickness 1.0μ-0.55μ. Most of these were pointed at both ends, while others ended more or less bluntly. Generally the short specimens were thicker and less pointed than the long ones. They have mostly a straight, elongated form; those which were bent were very few. Its surface is everywhere smooth; in no place angular. One sees in places, taken up in eosinophile leucocytes, rounded formations which in thickness and color resemble perfectly the formation in question, and which cannot be regarded as anything else but the spindles seen in the section transversely. The formations in question are consequently, according to their shape, to be likened to a true spindle. They appear in sections stained with fuchsin with few exceptions, spotted-like, as they are at times less stained in the center or at one or the other end, about which I will speak later. (See Plate I.)

Staining Conditions. — They are fuchsinophile, not acid-fast, but alcohol-fast; in long exposure to acid they lose their stain quickly. They are stained slightly rose with eosin, and also with Giemsa; but these two staining fluids give no contrast staining. Neither methylen blue nor Gram's give a positive result.

The best method that I have found so far is the following:

1. Staining with carbolfuchsin for three or four hours. (Better in incubator.)
2. After rinsing in distilled water for five or six seconds, stain in the following solution:

Saturated solution of picric acid	100.0
Indigocarmin	0.5

3. Wash in distilled water.
4. Differentiation in absolute alcohol.
5. Xylol balsam.

This method is in principle similar to Ohtori's method for staining tubercle bacilli. The difference consists only in the fact that by my method the treatment with hydrochloric-acid-alcohol is superfluous.

In successful staining the spindles stain with fuchsin red, collagenous tissue and nucleus with indigocarmin green, red blood cells reddish-yellow. Besides the spindles, the granules of the eosinophile leucocytes and Russell's bodies, should they be present, are also stained red. The red stain of the spindles and of the eosinophile granules is, however, not altogether the same, since the latter are distinctly darker stained than the former. (See Plate.)

The red stain of the spindles is generally not a proportionate one; they are in places stained weaker, so they appear more or less spotted. The pale stained portion, which can make its appearance anywhere, appears then as a shadow. The spindles, which on both ends have such weaker stained portions, make one think of a rod.

Heidenhain's iron-alum-hematoxylin method also gives a beautiful stain; the spindles with the eosinophile granules and nuclei are stained intense black.

Biologic Characters.—Histologically we notice above all that the spindles in the tissues are in intimate connection with eosinophile leucocytes. They are found most regularly within the bodies of the eosinophiles; few are found external to the latter. This condition facilitates exceedingly the discovering of the spindles in the tissues, especially when they are only sparingly present.

They are found exclusively in inflamed uveal tissue, and indeed appear often in the vicinity of the giant cells, where the eosinophiles tend to assemble. They always lie singly, and are therefore easily overlooked.

Chemical Characters. — They are soluble in ether-alcohol, likewise in acid and water. I have placed the sections, after freeing them from celloidin, for 12 hours in an acetic solution, and in boiling water for 15 minutes, without, however, being able to notice a marked difference in the numbers as well as in the staining quality of the

spindles. In warm one per cent caustic potash solution they become unstainable after five minutes. I have furthermore treated the sections freed from celloidin with antiformin; the spindles behaved the same as with the treatment with potash solution, as not antiformin-fast.

Frequency of the Spindles.—In order to know how often the spindles appear in sympathetic ophthalmitis, I have examined all the sections which had been kept in the clinic. With these I had at my disposal seven cases which all showed typically the picture of the disease. Among these seven I could prove the presence of the spindles only in five.

The number of spindles differ as to the case. Among five cases with positive findings I could in two cases find a moderate abundance, in others only a scarcity of spindles. When they are numerous their discovery is not difficult. I could, in one case which contained them most numerously, observe in one field 8-10 spindles. If they are sparingly present their discovery is a very painstaking task, so that after repeated examinations of a whole section we find only a solitary spindle. As to the presence of spindles in other inflammatory eye affections, I wish to remark here, that I have in no case observed them. As a control experiment I have examined three cases of phthisis bulbi dolorosa, three cases of nonsympathetic uveitis after perforating injury, and one case of tuberculosis of the iris and the ciliary body. In all these cases the result was negative. From my examinations up to this time, spindles appear only in sympathetic ophthalmia.

What are these spindles? Primarily one asks himself the question if they are not artificial products which through fixation and hardening have originated secondarily. To this I wish to remark at once that from the five eyeballs which have shown the positive test, four were fixed in Mueller's solution, and the other in the Orth-Mueller solution, immediately after enucleation. Of two eyeballs in which the test was negative, the one was fixed in Zenker's solution, the other in formalin. Undoubtedly the almost regular appearance of these in eosinophile leucocytes, if they can be found at all in the tissues, speaks decidedly against this conception that they are artificial.

That they are neither tubercle bacilli nor similar bacilli can hardly be doubted by their behavior towards acid and their external shape.

Are they not a crystal? According to their external appearance they resemble a crystal very much. It requires hardly further explanation that they are neither fat-crystals nor fuscineedles. The intimate relation which exists between the spindles and eosinophiles permits the conjecture that they have been formed thru melting together or crystallization of the eosinophile granules. This conception is so much more probable since, according to some authors, the so-called Charcot-Leyden crystals are believed to be crystallization products of these granules. Levy[9] could find, for instance, in 47 cases of nasal polyps 32 times the Charcot-Leyden crystals and 17 times in 29 cases in such individuals, who never had suffered from asthma. The crystals thereby have shown in their staining qualities a pronounced acidophile condition. They have also been in the tissues with the eosinophile leucocytes, with which they were numerously associated and intimately connected. Levy also remarks that the crystals are found to be more numerous when the tissue which is under investigation has been exposed primarily to spontaneous putrefaction.

My spindles and the Charcot-Leyden crystals are very similar in their staining conditions, as both are decidedly acidophile. Whether they act chemically alike is for the present not ascertainable, as the behavior of Charcot-Leyden crystals in hardened preparations had not heretofore been mentioned in the literature, as far as my studies are concerned. The Charcot-Leyden crystals are in fresh condition very easily soluble in acid, alkali and warm water.

Lubarsch[10] was also able to prove in the cells of the human testicle, small crystalline bodies, which were in hardened preparations soluble in boiling water and 50 per cent acetic acid, but insoluble in alkali. My spindles differentiate, therefore, from these small bodies thru their chemical behavior.

Are they not a kind of microorganism? The pathogenic bacilli, named *bacillus fusiformis,* have a spindle shaped form, and have been found heretofore in different diseases both local and general. The most important form of these spindle-like bacilli is the bacillus Vincenti and the one found by Babes[11] in scurvy. Similar bacilli are encountered also occasionally in the normal buccal cavity. All these bacilli distinguish themselves[12] thru their peculiar form, their spotted appearance in stained condition, and finally thru their inconstant size. They have, therefore, no similarity at all with my spindles, at least not in their external form.

That the spindles are not microorganisms is undoubtedly true. In the same manner there is no certain proof for their nature of a microorganism. To decide this question we have to wait till the time comes when their multiplication can be surely proven in some nutrient medium. The differentiation of the spindles from Charcot-Leyden crystals must also be left for future investigations.

The fact which, however, deserves special consideration is that the spindles are found very frequently only in sympathetic ophthalmitis. If these spindles were a kind of spindle-formed bacilli, and would appear sometimes as a saprophytic inhabitant of the normal buccal cavity, it would be not at all unnatural, that they would occasionally, in a perforating injury of the eye, infect the wound and produce sympathetic ophthalmitis.

While the true nature of my spindles is not at all clear at this time, and I certainly do not intend to assert that they are of any importance for the etiology of sympathetic ophthalmitis, I claim the privilege of now bringing to the knoweldge of the profession the result of my investigations, which at any rate are remarkable in their findings.

CONGENITAL TUMOR OF THE CORNEA OF DOUBTFUL CLASSIFICATION.

H. H. Stark, M. D.

EL PASO, TEXAS.

The case here reported seems unique in that the probable dermoid tumor was nowhere connected with the limbus. The reports on its pathologic anatomy and review of the literature bearing most directly upon it complete the paper. With four illustrations.

Uncomplicated tumors confined to the cornea, either congenital or acquired, are of so rare an occurrence that I feel the case I have recently seen may be worthy of reporting.

CASE.

A. A., Mexican, female, age 15; well nourished but of nervous temperament, reported to me on November 6, 1917, having been sent home from school by her teacher with instructions to see a doctor regarding a growth she had on her right eye, which she claimed had been there since birth. No family history could be obtained, both parents being dead.

On examination the following conditions were found:

Both lids were normal in shape and movement. The right eye was slightly smaller and deeper set in the orbit than the left, having a convergent strabismus of about twenty degrees, with no movement to the temporal side past the median line. The conjunctiva and sclera were apparently normal.

On the cornea was a growth protruding between the lids, with a perfectly round base of about eight millimeters in diameter, and about five millimeters high. It was bluntly conical in shape, and slightly flattened, horizontally, from lid pressure. The body of the tumor was light pink, the tip darker in color with faint stippling due possibly to exposure and inflammation. On examination with a loupe the stippling became faintly papillary in character, but no hairs could be seen.

Surrounding the tumor was a distinct area of clear cornea about three

Fig. 1. Congenital tumor of cornea, front view showing separation of tumor from the limbus.

millimeters wide on the temporal side, shading down to two millimeters on the nasal side, having what appeared to be a normal curvature. On the nasal side with the aid of a loupe could be seen one large, one medium and several finer vessels passing thru the cornea from the limbus, terminating in the tumor, but no clouding of the corneal tisue. Thru the clear cornea could be seen the iris, normal in color. The pupil was dilated evenly with atropin, and with an oblique view showed normal reflex of the fundus.

An interview with a relative with whom the patient was living confirmed the history that the tumor was congenital. She also said that it had increased in size during the last few years.

Photographs of the eye were taken, and a few days later, under a general anesthetic, the growth was removed. On picking up the tumor with forceps it was found to be very hard, requiring a firmer grip than ordinary tissue. After fixing, a cataract knife was passed along the base of the tumor at its juncture with the cornea, carefully working and pulling on the tumor, thinking there might possibly be a connection some place with the anterior chamber.

After loosening part of the base and pulling with considerable force, a distinct line of demarcation could be seen between the tumor and cornea, along which was passed the knife, easily peeling the growth from its attachment. About the center of the base of the tumor was a marked bleeding, coming from a point in the cornea. The bleeding continued for several minutes after the removal of the growth.

Examination of the cornea after the operation showed it to have a normal curvature and apparently a normal thickness and transparency. There was no sign of scar tissue or injury in any place. The healing was rather slow on account of the large area to be covered with epithelium. The spot in the center corresponding to the bleeding point remained red for at least two weeks, as though a blood clot had been formed, finally disappearing. At the time of the operation, blood was taken for a Wassermann test, which proved negative.

After healing, the pupil was dilated with atropin and an indistinct view of the fundus was obtained, but no abnor-

Fig. 2. Tumor of cornea from the side showing protrusion of tumor.

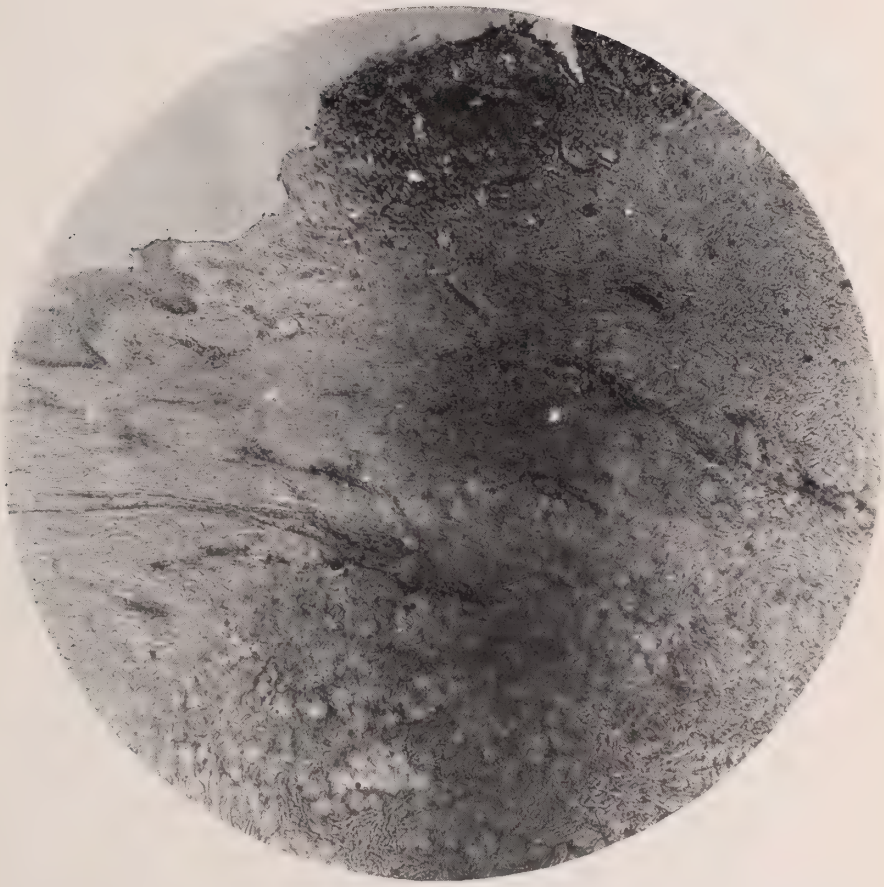

FIG. 5.—SECTION OF TUMOR SHOWING CONNECTIVE TISSUE MASSES AND FAT CELLS IN STARK'S CASE OF TUMOR OF THE CORNEA.

malities were found. The cornea at the present time shows a thick mottling of scar tissue rather than a dense scar, many places being so clear that a distinct view of the iris may be had. The eye was practically blind, no doubt from the fact that vision had never been developed. Now, seven months after the operation, there is no recurrence. The left eye was normal in appearance and vision.

Examination of the Tumor.

Much to my regret, I allowed eagerness on my part to determine the nature of the growth to prompt me to turn the tumor over to our local pathologist, with instructions to make frozen sections rather than to have serial sections made. The frozen sections were made from the center of the tumor and stained with hematoxylin eosin. Examination showed the tumor not to be of ordinary character and some of the millimeters in diameter and 2 or 3 millimeters thick, covered on one side with epithelium, the other side being the raw surface where it was peeled off the eye. The epithelium was roughened in places, containing elevations that might be classed as small papillae, but for the most part it looked as if it had been subject to considerable ulceration, with an attempt at healing. The whole specimen was hardened in formaldehyde. A small section was taken out through the center for freezing to section.

"On section the tissue was very firm, and the frozen block cut with difficulty, like cutting a piece of tough leather. Sections stained in hematoxylin and eosin, on microscopic examination showed a layer of fibrous tissue, covered by a fairly thick layer of stratified epithelium. The epithelium was somewhat irregular on the surface, and in the space beneath it there was considerable infiltration with small round cells. In none

Fig. 3. Eye after removal of tumor. Front view.

sections were sent to different pathologists for their opinions. Later, a part of the tumor was embedded in paraffin, sectioned and stained with van Gieson's stain and sent to the same men, these procedures using about two-thirds of the tumor. The remaining one-third was embedded in paraffin and sectioned serially.

Report of Dr. W. W. Waite, El Paso, Texas.—"I wish to report on the pathologic specimen removed from the eye of a Mexican girl. This specimen was a small button or disc-shaped tumor, 8

of the sections was there any suggestion of glands or hair. Plate II.

"The connective or fibrous tissue layer was made up of rather coarse fibres, stained deeply with eosin, in some ways suggesting smooth muscle tissue, but further examination showed there was considerable hyalin change. In the fibrous tissue layer there were small areas of fatty tissue. The fact that hyalin degeneration was present in the fibrous tissue shows that it was degenerating. To make sure that the fibrous tissue was really connective tissue, sec-

tions were stained with van Gieson's connective tissue stain, and the entire layer took the red stain. Another piece of tissue was embedded in paraffin and sectioned. The results from these sections were the same as those described above. In looking over a large number of sections, I did not see anything that resembled a gland or hair-follicle. My diagnosis of this case would be a *fibroma.*"

Report of Dr. F. H. Verhoeff, Boston, Mass.—"The two sections submitted to me show the tumor to consist chiefly of hyalin fibrous tissue. Its surface shows marked papillary outgrowths and is covered with squamous epithelium, beneath which in places there is a moderate infiltration with chronic inflammatory cells. At the base of the tumor there is an abundance of adipose tissue. Diagnosis —*dermoid tumor* of the cornea.

"The unusual feature of this case was the marked character of the surface; and the fact, apparently indicated by the photograph of the patient, that the tumor was not connected with the limbus, but was confined to the cornea. There are no sweat or sebaceous glands in the section, but these are not necessary for the diagnosis. It is possible, however, that other sections may show such glands. I have seen one similar case, in which, in addition there was an independent teratoid tumor of the bulbar conjunctiva." In a subsequent letter he states: "The large amount of fat tissue present in the other sections you sent me rules out a simple fibroma. You could call this tumor a dermo-fibro-lipoma if you wished, but it is essentially of the same nature as a dermoid."

Report of Dr. Allen J. Smith, Pathological Department, University of Pennsylvania.—Through the kindness of Dr. William Zentmayer, sections of this tumor were submitted to Dr. Allen J. Smith, Pathologic Department, University of Pennsylvania, who writes: "I must confess to an inability to recognize the tissues as corneal had I not been told of their origin. The epithelium is too thick, forms penetrating roots or pegs, and in its best places is not flat enough. I cannot distinguish a Bowman's membrane; the matrix is not lamellated, is too cellular, and in its vessels (of course, because of the fact the sections do not reach all the way through the cornea), I find no Descemet's membrane in its lining cells. True, too, in several of the sections, fat cells, as in isolated cells, occur in the matrix.

Fig. 4. Eye after removal of tumor. Lateral view.

"The cornea apparently had small nodosities or granular projections upon its surface, as small fibricular protrusions appear in the section covered by epithelium. The thickened epithelial layer, such nodosities, even the epithelium penetrations, and, of course, the fibrous tissue, especially the finer parts close to the surface, might well be explained as to the vascularization referred to, on the basis of a chronic inflammatory process, but I can scarcely think of the adipose cells in this relation. I feel this feature can only be explained by the suggestion

FIG. 6.—SECTION OF TUMOR OF CORNEA (STARK'S CASE) SHOWING PAPILLAE ON PART OF THE SURFACE.

you give me that the condition is a dermoid.

"With this idea that I have skin instead of, or added to corneal tissue, the thickening of the epithelium, the non-lamellated fibrous matrix, the presence of blood vessels, and particularly the presence of fat, are all in conformity, but I wish Dr. Stark could also find a hair or two or a skin gland in some of the material to complete the picture. I am inclined to agree very strongly that this is a dermoid, but I would urge further search for one of these structures as final proof, although I do not feel that failure to find one or the other bars the diagnosis, which stands more as the most probable condition, at any rate. I feel that a chronic inflammation has, however, co-existed, the swollen epithelial cells, the epithelial hyperplasia in producing the penetrating roots, the turgid capillaries and the cellular investments along these and some of the older vessels, and the dense fibrous tissue areas met with, I think, argue for this, and doubtless this has occasioned a little nodular papilla as well. I do not seriously question the *diagnosis of a dermoid,* but feel that he may be able to establish the point beyond the shadow of a doubt if he will continue the examination of the material."

Dr. Marcus Feingold, New Orleans, La. "The specimens submitted represent perpendicular sections through a meniscus-like growth of about 7 by 1.5 mm. The mass of the growth is made up of coarse bundles of connective tissue, closely packed and running in different directions, containing very few cells and blood vessels. It is covered by an epithelium similar to corneal epithelium, but containing decidedly more layers; no cornification can be seen anywhere. The epithelium runs smoothly over the growth but forms short down-growths and thickenings here and there to compensate for the slightly irregular surface of the underlying tissue. The epithelium is overlying the connective tissue directly; only in some short places is a more loosely arranged connective tissue interposed.

In a very few sections typical fat cells can be seen near the wound-surface of the growth, and extending from it into some spaces between the connective tissue. In a small area at the edge of the growth a decidedly papillary formation of connective tissue and epithelium is seen (Plate III), with arrangement of the blood vessels typical for it. Here some infiltration with cells is visible, the nature of which cannot be decided owing to the defective preparation. No satisfactory study of the connective tissue is possible.

The growth represents, therefore, a connective tissue tumor covered by epithelium; and may be considered as the result of scar formation following an intrauterine inflammation of the cornea or possibly as a product of adhesion between amnion and cornea."

After receiving these reports, serial sections of the remaining one-third of the tumor were made and carefully examined, all showing the same character of tissue as was found in the other part of the tumor. No signs of hair follicles or glands was found, nor do I believe there were any in the other sections.

CORNEAL TUMORS IN GENERAL.

Tumors of the cornea are divided as other tumors into malignant and benign, the malignant being sarcoma and epithelioma; the benign being fibromyxoma, papilloma, dermoids and teratoids.

In considering corneal tumors, Parsons[1] says:

"A review of the recorded cases of corneal tumors leaves one in great doubt as to their true status. No sharp line can be drawn between purely inflammatory conditions and many so-called growths. There is an even gradation from the simple corneal scar to the myxoma on one hand and the papilloma on the other. . . . The same applies with equal force to the new growths, both benign and malignant, for all are vascular, though in varying degrees, and derive their vessels from the limbus. Most doubtful of all are the malignant growths, especially the epitheliomata and the endothelial type of sarcomata."

He is justified in his contention that growths of any kind confined to the cornea are rare, as it is a well-known fact that the favorite seat of practically all tumors is found, on careful reading of

the literature, either astride the limbus or connected with the limbus in some way. This fact becomes more evident when one makes a search of the literature. In reviewing different articles on tumors of the eye, it was found difficult in many cases to determine from the description whether the tumor was confined to the cornea or had some connection with the limbus. It is true that only a slight connection with the limbus is necessary, because, as the growth increases in size, advancement is usually made over the corneal surface.

Many cases of reported corneal tumors are found, on careful reading of the article, to have connection with the limbus. Even many of those looking like pure corneal growths are questionable and should not be so classified. However, including doubtful cases, the number of tumors confined to the cornea is very small, in comparison with all tumors of the eye. A fairly good search of the literature was made classifying the tumors under the head of malignant growth, including sarcoma and carcinoma, papilloma, fibromyxoma, dermoids and teratomas, the result being as follows: malignant growths, 20; papilloma, 4; fibromyxoma, 1.

Of dermoids and teratomas there was none, unless we include multiple tumors of the eye, where one was situated on the cornea, the second on some other part of the eye. Even these are very rare. Just why there are so many more malignant than benign growths is a doubtful question. Two views may be taken on this point—first, that many of the malignant growths are simply degeneration of a former benign tumor; second, that the tendency is stronger with the oculist to report a malignant growth than one of a benign character. No doubt both of these views have a bearing on the question.

In considering this tumor, we may safely exclude malignancy. The history of the case and the histologic structure of the growth would exclude papilloma, leaving us only the dermoid and fibroid to be considered.

DERMOID TUMORS AND THEIR ORIGIN.

According to Parsons[2], "Dermoids are lenticular yellow or reddish congenital tumors, which occur astride the corneal margin, usually on the outer side, containing the elements of skin (stratified epithelium, hairs, sebaceous glands, etc.). They were described as early as 1742, and four cases were published by Wardrop in 1808. They were named 'dermoids' by Ryba in 1853. While commonest at the outer part, they occur rarely at any part of the limbus, even under the outer canthus. They are often associated with other congenital malformations—(according to Picqué, 27 out of 94)—colobomata of the lids, fleshy bands from the globe to the face, etc."

Various theories have been suggested for the explanation of dermoids. Ryba suggested failure of complete closure of the lids, with consequent cornification of the conjunctiva, and cited the correspondence of dermoids and lid-notch. This view is accepted by Bland-Sutton and Treacher Collins; the latter regards cryptophthalmia, in which the whole surface of the eye-ball is covered with skin, as the ultimate manifestation of dermoid development. Gallenga drew attention to the plica semilunaris, which in fetal life, covers the globe like its phylogenetic equivalent, nictitating membrane. He thought it might remain adherent to the membrane. Osborn thought the tumor might be a remnant of the epiblast which forms the lens. Van Duyse considered it was due to an adhesion of the amnion to the eye. While it is not the province of this paper to discuss the origin of these growths, it is worth considering, as it may be possible that both the theories of Ryba and van Duyse are correct; and that those showing true dermal character come from the lid, while those without the dermal characteristics come from the amnion.

CLASSIFICATION OF DERMOID TUMORS.

On the classification of these tumors many interesting and instructive papers have been written. Among the early ones is Gallenga[3], who classifies them as, first: pure dermoids; second, lipo-dermoids; third, mixed form or lipomata containing acinous or rather acino-tubular glands, or cartilage. Concerning the origin of the pure typical dermoids, Gallenga accepts Ryba's explanation, according to

which dermoids develop as the result of disturbed closure of the oblique facial fissures, and thereby also of the palpebral gap.

Saemisch[4] says that, "the dermoid of the conjunctiva is the designation usually applied to tumors which are congenital and closely related to the skin in their histologic features. They are accordingly to be interpreted as teratoid tumors. However, the histologic components of the skin may be unequally developed in individual cases, the epidermoidal structures of the skin, the hairs as well as the glands (sebaceous and sweat glands) being much more distinctly manifested in some cases than in others. The degree of development of the subcutaneous fatty cellular tissue is especially variable, being sometimes merely suggested, whereas on the other hand it may form the main bulk of the tumor. Nerves, vessels, and smooth muscle fibres are likewise seen variably developed in their growths; more rarely discs of cartilage have been noted. . . . Notwithstanding the great variability in the histologic behavior of these tumors, they share the common peculiarity of representing cutaneous structures which have been developed in the conjunctiva, although the individual tissue varieties of cutaneous character are by no means necessarily developed to the same degree. Hence it does not appear to be justifiable to select this factor as the criterion for a classification of these tumors, as suggested by Gallenga, but it would seem more appropriate to have the classification of these tumors on their topography."

Fuchs[5] says: "A dermoid tumor is a flat growth of a solid consistence, which, so to speak, straddles the margin of the cornea, being situated partly in the conjunctiva and partly in the cornea, with which latter it is immovably connected. It most frequently occurs on the external (temporal) side of the cornea. Histologic examination shows that the growth possesses the composition of the external skin. It consists of a stroma of connective tissue, covered with epidermis, and contains hair follicles and various glands. It is, so to speak, an island of skin upon the surface of the ball."

The latest and perhaps the most exhaustive paper on dermoids is that by Pignatari[6], who writes as follows:

"As shown by numerous reports in the literature concerning dermoids of the corneo-scleral junction, there is not one constant structure for these mixed teratomata. According to Gallenga's classification, which is adopted by the author, these growths are divided into several groups, as follows:

"A dermoid of the conjunctiva is a congenital tumor whose histologic structure has very close relations with that of the normal skin. Its volume is usually small, seldom more than half a nut; the color is usually whitish, often slightly pink or yellowish, a tint attributed formerly to the presence of fat, though this has been shown not to be the case. The form most common is a truncated cone; but hemispheric is not uncommon, and occasionally they may be pedunculated.

"The surface is sometimes smooth, sometimes slightly irregular; rarely it presents a series of small irregularities arranged similarly to those of the skin. Sometimes the surface of the tumor may become covered with fine drops of fluid while it is being examined; these drops come from small glands in the subjacent tissue, and their ducts may be seen by close inspection with the aid of a powerful loupe. The surface usually bears hairs, varying in length with the age of the patient. It is rare to see in children anything but a fine down.

"The site of the tumor is important; commonly they ride the lower outer part of the sclero-corneal junction; more rarely they are purely conjunctival; a completely corneal seat is the least common. In four instances only has the seat been the caruncle. The histology of these tumors shows their close relation to the skin; all the parts of the true skin are to be found; hair glands and sebaceous glands are almost constant; on the other hand, sweat glands are comparatively rare, though not so infrequent as they were held to be by the earlier observers."

Under the name of lipo-dermoids, Pignatari includes those forms which are congenital and have a superficial layer like that of dermoids, but which differ

in containing a large quantity of fat, as well as certain other elements, acinous glands and smooth muscle fibres, which are less frequent in this form. The normal situation of a lipo-dermoid, in which some 70 per cent are found, is between the insertions of the rectus superior and the rectus externus. The structure of these lipo-dermoids varies within wide limits; sometimes the dermal features predominate, sometimes the fat. Often there will be so little development of the cutaneous elements that they may be overlooked, unless series of sections are taken of the whole mass. In a considerable number of cases a mass of cartilage will be found in the deeper part.

The pure conjunctival lipoma is a tumor developed in the subconjunctival tissue and devoid of all cutaneous elements. Many of the cases which appear to be lipomata on clinical examination, prove to be lipodermoid when subjected to the microscope. Great difference of opinion still prevails between pathologists as to the constitution of lipomata, and on their congenital origin.

MIXED TERATOMATA.

As far back as 1888, Gallenga suggested this third division for these tumors, and placed in it those cases in which lipomata were found to contain acinous or acino-tubular glands, or remains of the semilunar cartilage. Later, Gallenga redivided this group into two: (1) mixed teratoma with mucous surface; (2) mixed teratoma with cutaneous surface. The origin of these is probably different from that of the tumors so far considered.

Mixed teratomata contain acino-tubular glands, and these glands often very closely resemble the lacrimal in structure. Gallenga and some others are inclined to consider them really derived from the lacrimal gland, and to be simple ectopia glandis; they reason thus from the fact that the secretion from the gland is neither wanting or abnormal. Gallenga thinks also, that the growth of this aberrant gland accounts in some cases for the presence of cartilage or bone, those fragments having been cut off from the orbital margin by the gland in its extension. Probably, however, in most cases the cartilage is derived from the cartilage in the membrana nictitans, which has become, in the course of development, adherent to the eye.

Concerning the development of teratomata, Pignatari accepts Gallenga's views in accordance with which the typical dermoid is a part of the lid margin which has become adherent to the globe, and has gradually become separated from the lids by the development of abnormal lines of division, which form furrows growing gradually deeper until the dermoid is cut off from the lid and remains a part of the globe. The other form of teratoma is due, in his opinion, to ectopia of some part of the lacrimal gland, which takes up a new position because of the faulty direction of some of its parts. The presence of amniotic bands is only a rare cause.

A comparatively large proportion of dermoids is associated with some faulty development of the eye lids or face. Presumably, coloboma of the lid is chiefly due to the adhesion of a part of the lid-margin to the eye and its separation afterwards; thus a gap is left in the lid, the coloboma, which is accurately filled by the dermoid.

FIBROID TUMORS.

The idea prevailing with practically all authors is that fibroid tumors originate from scar tissue, most of them being simply hyperplasia of this tissue. This is agreed to by Parsons[7], but he says there are cases which are apparently true fibroma. Regarding the structure, he says: "They consist of irregular bands of fibrous tissue, with scant flat and round cells."

CONCLUSIONS.

After reading the literature on corneal tumors and considering this case, I have come to the following conclusions:

(1) Corneal tumors occur less frequently than the literature would indicate.

(2) In order to be classified as a corneal tumor the growth must have no connection with the limbus at any place.

(3) That dermoid may be used as a

term to classify congenital tumors, even those of simple histologic structure containing no dermal tissue, hairs or sweat glands.

DETERMINATION OF MINIMUM LIGHT SENSE AND RETINAL DARK ADAPTATION WITH PRESENTATION OF A NEW TYPE OF PHOTOMETER.

JESSE WRIGHT DOWNEY, JR., M. D., F. A. C. S.

BALTIMORE, MD.

This paper reviews the principal hypotheses with reference to light and dark adaptation, and suggests a practical photometer, using a radioactive substance as a standard of comparison. With three illustrations, and experimental findings with this instrument.

The retina is the physiologic point of contact between the external stimulus, light, which the eyes require to convert the world without into a place of form and dimension, luminosity and color; and the final perception of these as "definite qualitative entities in consciousness." The conversion of the physical into a psychologic stimulus is brought about by demonstrable structural, chemic and electric changes engendered by the action of the light waves upon the retinal neuro-epithelial layer of rods and cones.

Reference to one monograph (J. Herbert Parsons, An Introduction to the Study of Color Vision, Cambridge, 1915) is sufficient to show the vast literature dealing with the complex elements, singly and combined, that go to make up this one phase of the visual act. The whole question may be roughly reduced to the one statement that all visual sensations are dependent upon the power that the retina possesses of adapting itself to, and converting into nerve stimuli, light vibrations of varying degrees of intensity.

The simplest example of light and dark adaptation of the retina is the experience of common knowledge, that if we pass from the bright sunlight into a dimly lighted room we cannot plainly distinguish objects until our eyes have become accustomed to this feeble illumination. If, again, we go out into the sunlight we are dazzled by its brightness, until the eyes have once more become adjusted to this degree of light. From the physical standpoint this is entirely a question of the intensity of the external stimulus. From the psycho-physiologic viewpoint, these phenomena are dependent upon certain material alterations which take place in the nerve cells of the retina, in turn exciting neuro-visual consciousness.

It is with this latter aspect that we are concerned, for we may assume that the external stimulus as such exists whether or not we have eyes to see; therefore, we may dismiss from consideration all the qualities of light as vibratory energy in ether, except its quantitative variability, on which depends the two great classes of sensation into which our consciousness of light may be divided, viz.: color sensation and colorless sensation.

Light vibrations are converted into nerve stimuli by the neuro-epithelial rods and cones which make up the outer layer of the retina. It is necessary to remember that there are no rods at the fovea centralis, but passing outward from the

central spot rods begin to make their appearance in increasing numbers, until at the periphery they far outnumber the cones. Parsons distinguishes three areas, as follows: The fovea centralis measuring 0.24 mm. to 0.3 mm. and subtending a visual angle of from 55′ to 70′. A rod free area measuring 0.8 mm. and subtending 3° 3′. The macula measuring from 1 to 3 mm. and subtending 4° to 12°.

Beneath the layer of rods and cones is the layer of pigment epithelium which, tho counted as part of the retina, is in reality outside. The cells of this layer are hexagonal in section and have processes passing up between the rods and cones. The cells contain minute needle shaped crystals of pigment. In the rods alone there is found the substance known as rhodopsin or visual purple, which may only be demonstrated after the eye has been in the dark, as it is completely bleached out by the action of light and is supposed to be reformed only in contact with the pigment cells. In the dark the pigment crystals are found in the cells close to the nucleus, but when the eyes are exposed to light they wander up into the cilia-like processes between the rods and cones. With these anatomic facts in mind let us consider the relationship that can be made out to exist bebetween the varying intensities of the external stimulus light and the resulting sensations elicited.

Let us assume, for example, that we are seated in a room brightly and uniformly illuminated from a source capable of gradual reduction in power until the room is in complete darkness. Under the bright illumination the eyes may be said to be light adapted, or *photopic* (nomenclature of Parsons), we see all objects distinctly and recognize colors. As the illumination decreases in intensity the yellows, normally the brightest colors, are exceeded in brightness by the greens, the blues become lighter and the reds darker. These changes in the relative brightness of colors constitute the well known Purkinje phenomenon. Finally, we can no longer perceive colors at all and objects take on various shades of grey. Later, we can only perceive the form of objects, and then comes complete darkness with no visual sensations. The eyes have been gradually becoming dark adapted or *scotopic*.

Under the conditions described we know that the following changes have been taking place in the perceptive end-organs of vision. In the photopic eye the rods are free of all demonstrable visual purple, and the pigment crystals are found in the cilia between the rods and cones. As dark adaptation proceeds the crystals of pigment migrate back into the cell body, and visual purple becomes evident in the base of each rod. On these anatomic facts there have been built up many theories, two of which must be briefly quoted, (1) The visual-purple theory of Edridge-Green and (2) the duplicity theory of v. Kries.

F. W. Edridge-Green (The Hunterian Lecture on Colour Vision and Colour Blindness, 1912), states his theory as follows: "A ray of light impinging on the retina liberates the visual purple from the rods and a photograph is formed. The rods are concerned only with the formation and distribution of the visual purple, not with the conveyance of the light impulses to the brain. The ends of the cones are stimulated thru the photo-chemical decomposition of the visual purple by light (very probably thru the electricity which is produced); and a visual impulse is set up which is conveyed through the optic nerve fibers to the brain. The character of the stimulus varies according to the wave length of the light causing it. In the impulse itself we have the physiologic basis of the sensation of light, and in the quality of the impulse the physiologic basis of the sensation of color."

Edridge-Green feels that he has proved his theory on evidence which he gives in his book. It is not necessary to go into this except to further quote: "that the visual purple is the essential factor in the retina which enables it to transform light into visual impulses. I find four depressions or canals which lead into the larger depression of the external fovea. These canals appear to have smaller branches and serve to conduct the visual purple into the part of most acute vision. The cones which are present in the fovea

have very long outer segments which would present a greater surface for photo-chemic stimulation. I have examined under the microscope the retinas of two monkeys which had been previously kept in a dark room for forty-eight hours. The yellow spot was the reddish part of the whole retina and the visual purple was seen to be between and not in the cones."

The duplicity theory of v. Kries (Parsons) states that achromatic scotopic vision is carried out thru the medium of the rods alone, the cones being the organs of photopic vision. In dark adaptation with low intensities of light, vision is performed by the rods stimulated by the visual purple, as the intensity of the light increases the liminal stimulation values for the cones is exceeded, and vision is carried out both by the rods and cones (chromatic scotopia). At still higher light intensities vision is carried out chiefly or wholly by the cones (photopia), but whether the rod effects are added to the cone effects, or are abolished, is as yet uncertain.

It will be seen that the formation of the visual purple is, at least, the basis of dark adaptation. In everyday life there is always a moderate amount of scotopia present which is constantly varying to meet the requirements of the moment. We cannot perceive colors unless the light stimulus is above a certain intensity whose liminal value Parsons calls the specific or color threshold. Below this is the colorless interval of light perception, which increases with the amount of dark adaptation present. It is with this interval that my studies are chiefly concerned.

In every physiologic process there is a stimulus which excites, and a resulting reaction, or sensation. There is, of course, a more or less constant relationship between the stimulus and the reaction; and in any investigation it is usual to reduce the external stimulus to its simplest form and then study the resulting sensations, or to observe the simplest reaction that can be elicited by a variety of stimuli. The simplest visual sensation that we can have is the recognition of light, and the simplest stimulus is one that will just produce this reaction under approximately known conditions of retinal adaptation.

It occurred to me that the radioactive preparations so extensively used in the manufacture of luminous watch-dials and other instruments, would furnish an ideal light stimulus of constant value and low intensity, and with the coöperation of the "Cold Light Mfg. Co." of Denver and New York I obtained a series of discs of the radioactive substance which they put out under the trade name of "Marvelite." This substance is sulphid of zinc impregnated by radium: the latter constituent I have proved to my own satisfaction by numerous photographic experiments.

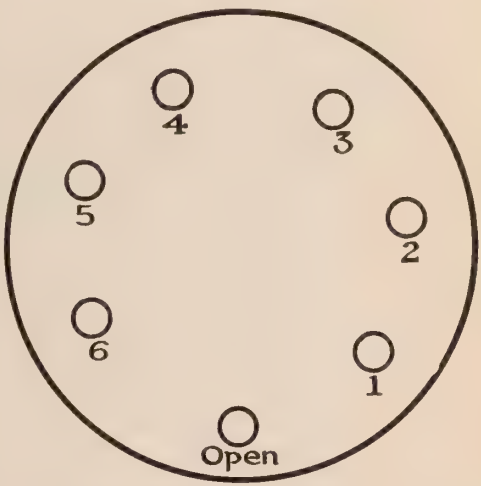

Fig. 1. Disc with openings carrying "Marvelite" exposed or covered with varying thicknesses of celluloid.

The Cold Light Mfg. Co. has instituted photometric measurements concerning the compound, and so far they have been able to determine that there is a rapid initial increase in the luminosity of the radium luminous compounds, followed by a decrease over a period of about six months, the rate of decrease then becomes slower and and slower, until at the end of one year the luminosity attains a value which is sensibly constant. The "Marvelite" discs which I am employing in my ex-

periments have been in my possession for a year.

As my experiments were to be along clinical lines I have calibrated these discs in the following manner. One was chosen as a standard which would just give the sensation of light as soon as I had passed from a well lighted room at midday into a photographic dark room. This disc is considered the minimum light stimulus to the light adapted eye. By photographic exposures I obtained a series of discs of similar intensity and by covering them with layers of No. 5 opaque white celluloid I determined, by experiments carried out at night after two hours in an absolutely dark room, that my minimum lightsense in full dark adaptation was represented by the standard disc covered by five layers of the celluloid.

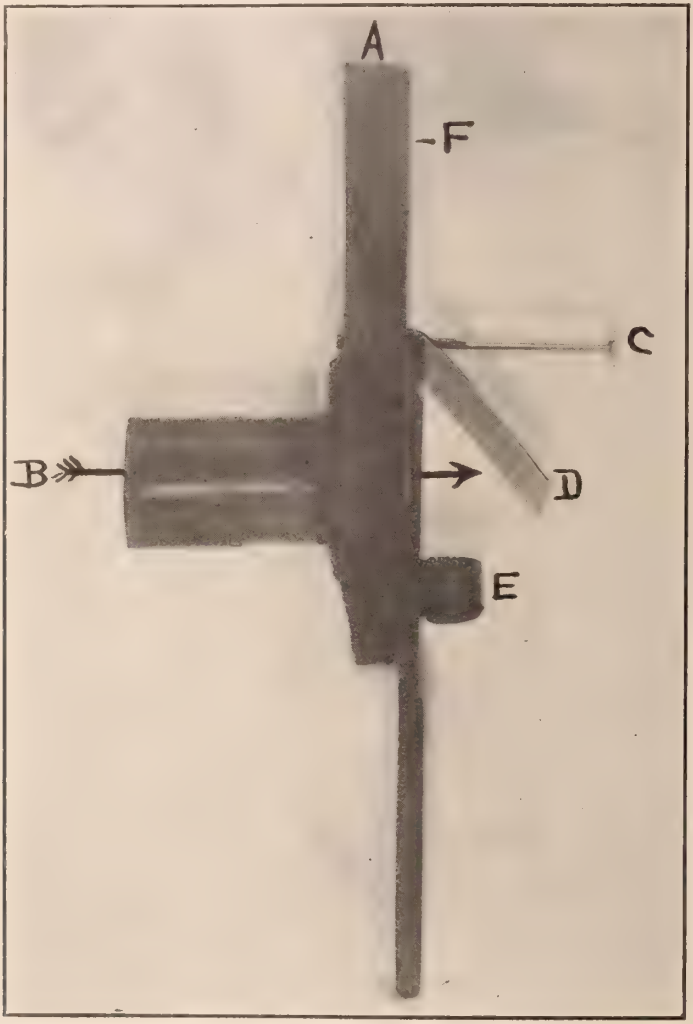

Fig. 2. The photometer described in the text. At F there is an opening through which may be read off the number of the "Marvelite" disc which is before the eye.

Six of these discs were then mounted on a circular plate (Figure 1), Disc No. 1, being the uncovered "Marvelite Button" accepted as the minimum effectual stimulus for the photopic eye. Disc No. 6 covered with five layers of celluloid being the minimum light stimu-

lus under full dark adaptation or scotopia. Discs Nos. 2, 3, 4, 5 and 6 being covered with 1, 2, 3, 4 and 5 layers of the celluloid. I have, therefore, six light stimuli of different degrees of intensity. The following apparatus was then constructed and certain experiments undertaken:

Figure 2 is a photograph of the photometer. The large wheel (Fig. 1) is mounted in the Box A and can be revolved before the eyepiece B by the handle C. When the opening in the wheel is before the eyepiece the observer is, of course, looking straight thru the instrument against the reflector D, which is covered with greenish blue paper to correspond with the faint greenish glow exhibited by the "Marvelite" discs of the higher intensities. The object E on the handle of the instrument is to hold a small electric light for experimental purposes to be later described. The "Marvelite" test discs are 7 mm. in diameter. The instrument is generally used at 10.5 cm. from the eye. The retinal image is therefore 1 mm. and subtends a visual angle of 4°. Figure 3 represents the "blinders" which are used in the application of the test. The slides are easily removed and the photometer brought into position and kept light proof by a leather cuff.

Let us for the moment anticipate the many problems involved and assume that the instrument is of accepted usefulness. The "blinders" are adjusted with the shutters out of the eyepieces. One shutter is replaced and the instrument is adjusted over the other eye-tube. The test object wheel is set at "open" and the observer is told to watch the round spot of light. The "Marvelite" disc No. 1 is now quickly turned into place and the individual should immediately see it. The actual test of the dark adaptation is made as follows. The "blinders" are closed and the patient is asked to keep the eyes shut. At the end of ten minutes the photometer is adjusted over one eye and the individual is asked to say when the light spot first becomes visible. The test-wheel is now slowly revolved so that the "Marvelite" discs of the weak intensities first appear before the eye. The moment the patient says, "now I see light," the number of the disc is noted and the result written in the form of a fraction the numerator of which denotes the patient's mini-

Fig. 3. The "blinders" which are fastened over the eyes.

mum light sense, the denominator the minimum light sense which numerous observations have indicated as the normal. After ten minutes in complete darkness, disc No. 5 should be seen. If the dark adaptation of the retina is normal the test is completed in ten minutes; this statement, I think, can be substantiated by the experimental work now to be described.

Experiment 1. — Is the Marvelite Disc No. 1 the minimum light stimulus for the light adapted or photopic eye? Under ordinary conditions of everyday room illumination, yes. Under full light adaptation or what may be termed light excess induced by looking at the clear sky on a bright day, no. But even under the latter conditions disc No. 1 becomes evident within thirty seconds after the eye is brought from light into darkness, which proves that the range of light adaptability even in the photopic eye is exceedingly wide. This has been proved by experiments on many individuals. If we accept Edridge-Green's theory, then we must assume, that in the light exhausted eye the visual purple is very rapidly reformed, or that it still preserves photochemic activity even in the bleached out state.

Just how greatly the sensitiveness of the retina to light is increased by dark adaptation is proven by the comparative luminosity of the "Marvelite" disc No. 1 under photopic conditions and in scotopia. In the latter state of the retina the disc is sufficiently intense to illuminate the tube of the eye piece and to slightly raise the minimum light sense. For example, if Disc No. 1 is viewed under full scotopia and the test wheel is then quickly turned to disc No. 6, the latter cannot be distinguished for a few seconds, altho it represented the minimum light sense just a few moments before. Under photopia disc No. 1 can just be discerned as an extremely faint light.

Experiment 2.—Dark adaptation is very rapid at the beginning of the process and exceedingly slow toward the completion. When the light adapted eye is brought from light into darkness disc No. 2 will become visible in about thirty seconds. Disc No. 3 requires at least ninety seconds of dark adaptation. Disc No. 4 is seen in from three to four minutes and after ten minutes disc No. 5 is just discernable. After ten minutes of dark adaptation the process becomes very slow. In observations made at midday disc No. 5 represented the minimum light stimulus after ten minutes; this was not lowered during an hour's experimentation, altho the luminosity of disc No. 5 became appreciably greater. After two hours observation in a dark room disc No. 6 could just be seen.

As Parsons has said, experiments in dark adaptation are much influenced by the condition of retinal adaptation at the beginning of the observations. I have found that if the individual to be tested has been sitting in a dimly lighted room his photopic minimum light sense may be represented by disc No. 2. With this in view I experimented with a small electric light mounted on the back of the photometer with the idea of bringing all eyes to the same degree of light adaptation before beginning any tests. This has been found unnecessary for the reason that dark adaptation, according to my observations, progresses with definite constancy within all periods under an hour. Disc No. 2 as the minimum photopic light sense only indicates that there is already that amount of dark adaptation present; disc No. 5 may become the minimum light stimulus in less than ten minutes, but beyond that time there will be no appreciable lowering of the light sense, certainly not within the time that one has to devote to a clinical test.

To obtain uniform results it is well to allow the patient to sit in a moderately lighted room for a while before the test is to be made. The photopic minimum light sense is then tested by bringing the instrument before the eye, the patient should immediately see disc No. 1. If there is some slowness in this, beyond sixty seconds, it is indicative of slow dark adaptation. The blinders are then put on and the patient allowed to wait for ten minutes. At the end of this time each eye is tested and

disc No. 5 should be seen. If disc No. 5 is seen the test may be discontinued and the dark adaptation noted as normal. If disc No. 4 represents the minimum light sense after ten minutes the test should be continued for ten minutes longer, when, if disc No. 4 still represents the minimum light sense, the result may be noted 4/5 and dark adaptation considered as "slow." A minimum light sense below disc No. 4 is considered "abnormal."

For the time being I have adopted the following chart to preserve a record of examinations.

	Min. Light Stim.	Dark Adaptation
Immediate	R. Disc. No.	
	L. Disc No.	
After 10′	R. Disc No. /5	
	L. Disc No. /5	
After 20′	R. Disc No. /5	
	L. Disc No. /5	

Remarks:

Experiment 3.—Dark adaptation occurs in each eye independent of its fellow and is not influenced by light adaptation of the other eye. One eye was kept in darkness for one hour, the other was left open, the experiments being made in a brightly lighted room at midday. Dark adaptation proceeded as heretofore described, disc No. 5 becoming visible in ten minutes and remaining the minimum light stimulus during an hour of further experimentation. Ordinary light stimulus of the other eye had no influence on the dark adaptation of the other eye. Excessive light stimulation of the open eye, e. g., looking directly toward the sun, had no appreciable effect on the dark adapted eye, except that for a moment the dazzling occurring in the light adapted eye seemed to confuse the dark adapted eye. This seemed more the result of the vast difference in the cerebral impressions than any effect on the retina, as the disc could be seen surrounded by a halo of after-dazzling.

Experiment 4.—Dark adaptation of one eye does not hasten dark adaptation in the other. After one eye had been kept in the dark for one hour, the other eye was closed and frequent observations made. It was found that dark adaptation proceeded in exactly the order before noted, that is to say it took ten minutes to bring the sensibility of the retina down to disc No. 5.

Experiment 5. — Dark adaptation proceeds equally in both eyes. If both eyes are tested simultaneously it will be found that dark adaptation is the same in each eye after the same period of time. This has been confirmed by numerous tests and, therefore, I feel that it may be stated that dark adaptation, altho an independent process of each eye, is an extremely constant and uniform chemico-physiologic process. If, in clinical determinations, one eye is found to be different from the other, after the same period of time, it is more than suggestive that there is some abnormality in the retinal adaptation.

Experiment 6.—Is there a summation of effect in the dark adapted eyes? Some observers have found that the minimum light stimulus required is less with binocular vision than with monocular vision. Working with these light stimuli of exceedingly low intensity I have not been able to confirm these findings.

Experiment 7.—Full dark adaptation is very quickly overcome by exposure of the eye to light. If, after full dark adaptation, the eyes are completely exposed to light, dark adaptation will be overcome in thirty seconds at the most; that is to say, that the minimum light stimulus will be raised from disc No. 5 to disc No. 1, and it will again require the minimum ten minutes to bring the minimum light sense down to disc No. 5. In other words, the bleaching out of the visual purple is very rapidly accomplished if the whole retina is exposed. If, however, only a restricted portion of the retina is exposed to light, the minimum light sense of that portion of the retina is raised, but very quickly regains its minimum light sense. This, to my mind, rather confirms the theory

of Edridge-Green that there is a flow of the visual purple.

Experiments in regard to this were conducted in the following way: Both eyes were kept in the dark for twenty minutes so that the minimum light sense was represented by disc No. 5. Then the blinders were entirely removed and the eyes exposed to bright daylight for thirty seconds; the blinders were then replaced and it was found that the minimum light sense had been raised to disc No. 1. Furthermore, it required the usual ten minutes to again lower the light sense to disc No. 5. After full dark adaptation was again obtained the eye was exposed to a bright light thru a small aperture (5 mm.). This raised the minimum light sense to disc No. 1, but within sixty seconds the minimum light sense was again disc No. 5. In my opinion dark adaptation proceeds regularly over the whole retina. It may be locally bleached but this portion is again quickly sensitized by a flow of the visual purple to the spot, rather than by immediate reformation, otherwise it would require a much longer time to lower the light sense of the restricted area. From these experiments I am inclined to believe that a test of a restricted portion of the retina, such as is made by my photometer, is sufficient to judge the adaptability of the whole retina.

Experiment 8.—Is there any dark adaptation at the central part of the retina? It has already been noted that Parsons distinguishes three areas in this part of the retina, the fovea, a rod-free area and the macula containing a few rods. Used at 10.5 cm. from the eye the 7 mm. test object subtends a visual angle of 4°. This would overlap the rod-free area slightly as this portion is estimated by Parsons to subtend 3° 3′. On the other hand it covers the minimum area allotted to the macula proper of from 4° to 12°. In the discs of low intensity the area of the disc is less than 7 mm. As these discs do not emit any divergent radiations and can only be perceived as light "spots" of very low intensity, irregular in outline and not luminous in the periphery, I calculate their diameter to be about 5 mm. *Undoubtedly there is marked dark adaptation at the macula and if the size of the discs is reduced to* 5 *mm, dark adaptation can be shown to be present to the same degree in the rod-free area.*

If, however, the discs are viewed thru a pinpoint opening, thus reducing the visual angle practically to zero and making visibility entirely a question of luminosity, disc No. 2, even under complete dark adaptation, becomes the minimum light stimulus. I do not find, however, that the light sense is lower than disc No. 2 even in the extramacular region when tested with the pinpoint disc. I have reached the conclusion, therefore, that there is marked dark adaptation at the macula and in the rod-free area thereof, if the test-object is sufficiently large to subtend a definite angle. At the exact fovea, or in the periphery for that matter, when probably a few cones are stimulated by the point of light, there is very slight dark adaptation below the minimum light sense of the photopic eye. Conclusions in this regard are as yet uncertain. This particular phase of the question is open to much further investigation.

Finally, the work which I present at this time, is to a large degree confirmation of the findings of others; the instrument and the experiments are admittedly elementary.

The manufacturers of "Marvelite," with the coöperation of the United States Bureau of Standards, are making a scientific effort to standardize the luminosity of their product. It is probable that they will be able to produce a radiant substance of uniform value, which can be accurately calibrated. Clinically I have used the test for a year and have found the results extremely interesting and worthy of further study. These reports with further experiments I reserve for a future communication.

COMMON CHANGES IN REGULAR ASTIGMIA AND THEIR CAUSES.

EDWARD JACKSON, M. D.

DENVER.

This paper points out the error of supposing astigmia remains unchanged throughout life. Tabulates the changes found in 1,294 eyes remeasured after five to seventeen years, and the relation of corneal to total astigmia. With one diagram. Read before the Section on Ophthalmology, American Medical Association, June 12, 1918.

The first reported cases of astigmia were of high degree, so that moderate changes in the amount or meridians would not be very noticeable. The first correcting lenses, determined with considerable difficulty, were accepted as an accurate correction thruout life, except in the case of the astronomer Airy,[1] who remeasured his astigmia after nearly 20 years and found it had somewhat diminished. As we would express it today:

His correction of —6.5 ⌒ —5.5 cyl., had changed to —4.5 ⌒ —4.0 cyl.

Donders[2] classed the great mass of cases of astigmia as congenital, recognizing as acquired astigmia that depending on disease, or injury, or incision of the cornea, or upon traumatic displacement of the crystalline lens. He states, "In the great majority of cases it is congenital."[3] This thought was dominant in all his writings on the subject. He implies some skepticism as to the change in Airy's case when he says: "With a man like Airy we may assume that he observed for his farthest point with unaltered accommodation; otherwise we should venture the supposition that, in his earliest observations, in consequence of accommodation on the approach of the point of light, the myopia in the vertical meridian had turned out too great, whereby the recession of the farthest point with the increase of years (which certainly with the existing degree of myopia is extremely rare), should only apparently have taken place."

Knapp's[4] early observations with the ophthalmometer revealed the corneal astigmia unchanged during the brief time over which they were repeated. Javal's[5] statistics dealt with single observations upon each case. The same is true regarding the statistical record of 806 astigmic eyes published by Burnett.[6] The thought of ophthalmologists regarding astigmia was given a strong bent toward the conception that the astigmic condition of an eye was permanent. It was believed to be a congenital characteristic, that each eye carried from the cradle to the grave, unless altered by some accidental circumstance. This was in strong contrast to the earlier writings of Donders and others regarding the increase of hyperopia with age, the progressive tendency of all cases of myopia in the early part of their course, and the senile myopic change that gives second sight.

Early in his work on ametropia, the writer encountered some rather striking cases of progressive hyperopic astigmia, including his own eyes which were repeatedly measured under different cycloplegics. A series of 18 cases of such change was reported to the American Ophthalmological Society in 1890.[7] Attention was also given the changes in astigmia following cataract extraction, and other corneal incisions.[8]

Early in these studies of astigmia, the impression arose that the common belief in its permanence was not well grounded; and the study of this subject was begun by the observation of changes in astigmia presented by patients returning for the remeasurement of their refraction. It was interrupted after a few years by removal from Philadelphia, so that patients previously measured no longer returned for reexamination. These studies, resumed in Denver with a new set of patients, have now been continued for 20 years, and a sufficient number of observations has accumulated to afford a basis for a statistical

study. These include notes on 1,294 eyes of 648 patients who have had their ametropia remeasured after periods of five to seventeen years. All cases of operative or other injury of the eyeball, or of keratoconus or other ocular disease except eye strain, have been excluded. The average period over which the observations of the refraction extended was eight and two-thirds years. Of these eyes 421, or 32.7 per cent, showed less than 0.25D of change in the amount of astigmia present; and 873, or 67.3 per cent, showed at least that much change in their astigmia, as measured for the correction of their ametropia. Of these latter, 394, or 31.2 per cent, showed 0.50D, or more change in the amount of their astigmia.

These cases in which the change was 0.50D. or greater were made the basis of a further statistical study as to the general direction of this change in the astigmia and the ages at which it occurred. The results of such study are embodied in Table I.

The first column gives the ages of the patients thus: Those given as 10 years were under 10 years when first examined; but the large majority were over 10 years at the last examination. Those given as 20 years were between 10 and 20 when first examined, but most of them over 20 when last seen. This plan is followed thruout the table, except that the line for 70 years includes all patients that were over 60 years when first examined.

Column A gives the number of eyes in which the change was an increase of astigmia with the rule, or a decrease of astigmia against the rule, or a passing of astigmia against into astigmia with the rule. Astigmia with the rule was made to include all cases in which the axis of the convex correcting cylinder was placed within 30° of the vertical, or the axis of the concave correcting cylinder within 30° of the horizontal; i. e., plus axes between 60° and 120°, or minus axes between 150° and 30°. Astigmia against the rule includes all cases in which the axis of the convex correcting cylinder lies between 150° and 30°, and the axis of the concave correcting cylinder lies between 60° and 120°.

Column B gives the number of cases in which the change was a decrease of astigmia with the rule, or an increase of astigmia against the rule; or where astigmia with the rule changed to astigmia against the rule as these terms are defined in the preceding paragraph.

Column C gives the number of cases of oblique astigmia in which the change was 0.50D. or more in amount, and in which the direction of the meridians for either convex or concave correcting cylinders lay between 30° and 60° on the one hand, or between 120° and 150° on the other.

TABLE I.

	A		B		C		
Age	Cases,	Per Cent	Cases,	Per Cent	Cases,	Per Cent	Totals
10 years.....	17	55	10	32	4	13	31
20 years.....	30	33	51	55	11	12	92
30 years.....	24	28	55	63	8	9	87
40 years.....	14	16	59	71	11	13	84
50 years.....	13	22	42	71	4	7	59
60 years.....	7	25	19	68	2	7	28
70 years.....	2	15	10	77	1	8	13
	107	27	246	62.5	41	10.5	394

From this table it appears that of this 394 eyes (31.2 per cent of all eyes) that showed a change of 0.50D or more in the amount of their astigmia, a majority, 62.5 per cent showed change toward astigmia against the rule, 27 per cent showed a change toward astigmia with the rule, and 10.5 showed changes in astigmia which remained or became oblique.

When we come to consider the distribution of these changes thru the different periods of life, the percentages show certain unmistakable tendencies. In early life, increase of astigmia with the rule, or the tendency in that direction, predominates, affecting 55 per cent in the first period. But as life advances, this tendency becomes less frequent, until in the last period it is shown in only 15 per cent of eyes. On the other hand, the tendency for astigmia with the rule to diminish, or the tendency toward astigmia against the rule, increases as life goes on. In the first period, it was shown by only 32 per cent. But in the last period, it was manifest by 77 per cent of eyes that remained without recognizable change in amount thruout the period they were under observation. The proportion that remain unchanged is least during the period of growth, but is considerable at all times of life, varying from 23 per cent before 10 years to 39 per cent after 50 years.

It must not be forgotten, however, that this diagram represents only the changes that occur during an average period of eight and two-thirds years. This is only one-fifth of the average life of these patients. It is extremely probable, if not absolutely certain, that many of this 32.7 per cent that showed no change in the amount of astigmia during the period

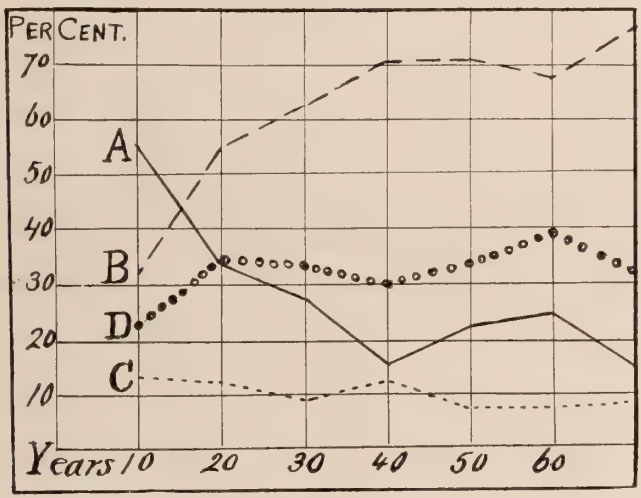

Figure 1.

the eyes examined. On the other hand, the number of cases of astigmia that vary in amount but remain oblique does not vary much (less than 4 per cent from the average of 10.5 per cent) thruout life. These facts are most easily grasped when presented graphically as in Fig. 1.

While these opposing tendencies are unequally represented, or predominate at different ages, it must be noted that each of them is represented at every period of life. There is no period of life at which any change of astigmia may not occur, quite apart from trauma of any kind, or from recognizable ocular disease. In Fig. 1 has been added a fourth line D showing the number of of observation have or will experience such changes at other periods of life.

CAUSES OF CHANGE IN ASTIGMIA.

It is generally assumed that the eye presents three dioptric surfaces bounding its dioptric media. But to the anterior surface of the cornea and anterior and posterior surfaces of the lens must be added the posterior surface of the cornea, and the surfaces bounding the different layers of the crystalline lens. Each layer of the crystalline lens has its individual index of refraction, differing from that of every other layer, so that each layer constitutes a distinct dioptric medium; and every one of

these dioptric surfaces may be astigmic.

It is customary to speak of the total astigmia of the eye as the resultant of its corneal and lenticular astigmia. But Tscherning[9] points out that this is not strictly exact. He calls the astigmia due to the anterior surface of the cornea the ophthalmometric astigmia; and the other possible factors that unite to cause the "subjective" or total astigmia, he groups as together causing what he calls the "supplementary" astigmia. Any difference between ophthalmometric and subjective astigmia is to be counted as supplementary. Let us consider whether these changes in astigmia are due to changes in the ophthalmometric or the supplementary astigmia. This may be detected by comparing the ophthalmometric readings with the total astigmia.

Ophthalmometric readings admit of a certain error of observation that makes differences of 0.25D or 0.50D too small to give reliable results. Those eyes were therefore selected that showed a change of 1D or more in the amount of astigmia for a study that might indicate where the change was located. The successive ophthalmometric readings have all been made with the ophthalmometer of Javal and Schiötz as made by Goubeaux of Paris, model of 1889. As before noted, all cases of distinct keratoconus have been excluded.

The following cases have been selected as being all in which the change of astigmia observed amounted to 1D or more. They illustrate the different relations between the ophthalmometric changes and those noted in the subjective astigmia. In the first group, the changes in anterior corneal surface show some correspondence with the changes in the total astigmia. In a few the change of corneal surface is exactly such as would produce the change in subjective astigmia. In other cases, the correspondence is not so exact, but evidently the anterior surface of the cornea has been one factor in the changes that have altered the astigmia. Under the case number is given the age of the patient when first examined and the age at the last examination. In the second column is given the ophthalmometric astigmia, and in the third column, the subjective astigmia found at the same time. R. and L. indicate the right and left eyes.

The cases in the following group show wide discrepancies between the changes in the ophthalmometric readings and the changes in total or subjec-

tive astigmia. In some cases, the two changes have been in opposite directions, so that the change in astigmia is clearly due to some factor other than the change in the anterior corneal surface.

	L.+0.75 cyl. ax. 150°	+0.25	L.+1.50 cyl. ax. 170°	+0.25

In the third group are included cases in which the changes in one eye would place the case in the first group, but the changes in the other eye are such as have occurred in cases of the second group. They emphasize the fact that even in the same patient, at the same time, differing factors may be working to produce changes of astigmia.

In examining Group A, it will be noticed that among the 28 eyes included, 24 showed the change to be one of increase of the astigmia; and that 15 showed increase of astigmia with the rule and 9 against the rule. The 4 in which the astigmia diminished were all cases in which it was changing from with to against the rule. These general tendencies hold good regarding lower degrees of astigmia, in which, however, there is a greater chance of error. So far as these statistics indicate, the changes in the anterior surface of the cornea generally tend in the direction of relative increase of curvature in the vertical meridian, altho to this rule there are exceptions.

Examination of Group B shows that where the change in total astigmia depends chiefly on a change of the supplementary astigmia, the corneal curvatures not showing any corresponding change, the tendency is generally toward astigmia against the rule, this being the case in 16 of the 22 eyes given in that group.

With regard to Group C, which includes 6 cases, we find that in the eyes in which the total corresponded to the corneal astigmia, 3 are with the rule, and 1 against. While in the eyes in which the change of corneal and total astigmia did not correspond, 3 are with the rule, 3 against; and 2 changing from with the rule to oblique, which has the same significance as changing from with the rule to against the rule.

In all three groups, therefore, it appears that the tendency is for astigmia to increase with the rule by increase of the corneal astigmia; and to increase against the rule by increase of the supplementary astigmia.

As to congenital astigmia, there is a sense in which a large proportion of cases may be regarded as congenital in origin. The work of Steiger[10] upon the heredity of ametropia has demonstrated what many observers had believed, that a tendency to astigmia exists in many families. Spengler[11] reported such a tendency in the family of Javal. Out of such a congenital tendency undoubtedly a large proportion of cases of astigmia develop, just as a congenital tendency may determine that in certain persons the hair will get white at an exceptionally early age, or that glaucoma or cataract will develop.

But many of these cases of astigmia of congenital origin differ entirely in their history from such congenital defects, as microphthalmos, or coloboma of the iris, or congenital color blindness. It is certain that in some of the cases the astigmia, although due to a congenital tendency, develops during life. The large proportion of children in whom the astigmia changes after they reach an age when it comes to be accurately measured, and the proportion of these in which the subjective astigmia corresponds to the form of the anterior corneal surface, indicates that many cases of "congenital" astigmia arise during the period of growth. Nor can it be claimed that the corneal development is the only factor in producing these cases of astigmia. In some of them an asymmetric growth of the lens is the most logical inference.

The progressive increase in the number of cases of astigmia changing from "with the rule" to "against the rule" is perhaps the most striking fact brought out. This is not at variance with the recorded experience of others. The statistics of Nordenson[12], which showed such a large percentage of corneal astigmia with the rule were based upon the examination of school children. It was about the time of their publication that the great preponderance of astigmia with the rule was generally accepted. Knapp's[13] original measurements of the cornea found among nine cases one in which a flatter meridian was vertical, and four in which it was more or less oblique. Donders'[14] fifteen cases show one case in which the meridian of greatest refraction was at 2°, another at which it was at 17°, and one at 172°; and in which all but five were the eyes of persons under thirty years of age.

In 1891, de Schweinitz[15] reported one hundred cases of astigmia contrary to the rule. Of his patients, 30 per cent were under forty and 70 per cent over forty. In 1903, Bennett and Clemesha[16] published a study of astigmia, in which they gave the proportions of the different forms of astigmia found at difrent ages. They found that among persons in the first decade of life, 88 per cent showed astigmia with the rule, while after seventy less than 30 per cent showed astigmia with the rule, and 63 per cent showed astigmia against the rule.

In this paper nothing has been said of changes in the meridians of astigmia, except regarding the three general classes of "with the rule," "against the rule," and "oblique." In Case 16 the change in total astigmia was only 0.25 D, but the change of 75° in the meridians of each eye made it a re-

versal of astigmia, equal in significance to a change of 1D in the amount. But changes in the meridians may be so readily produced by slight changes in one of the factors entering into the total astigmia that a study of changes in the direction of the axis of the correcting cylinder measured in degrees would be more confusing than helpful. An examination of these changes confirms observations based on the amount of rough change of axis; but shows that astigmia is even more variable than the facts here brought out would seem to indicate.

CONCLUSIONS: The facts before us demonstrate that astigmia is liable to change at any period of life. In childhood, it frequently increases because of the increased asymmetry of the anterior surface of the cornea. Such change is usually in the direction of relatively greater curvature in the vertical meridian. But this change may occur at any time of life. In childhood, also, the astigmia sometimes changes because of change in the other dioptric surfaces of the eye; and changes due to this cause become more and more frequent as time goes on. Such changes cause "astigmatism with the rule" to become the exception in the latter part of life, its opposite being now the rule.

This fact makes these generally understood terms entirely inappropriate, and they should be replaced by others, such as: *Direct,* with the meridian of greatest curvature approximately vertical; *inverse,* with the meridian of greatest curvature approximately horizontal, and *oblique* in the same sense in which it is used in this article.

Astigmia is congenital chiefly in the sense that a tendency to asymmetric refraction exists, which works itself out at some stage in the development of the individual.

The variety of the changes that may occur in astigmia point to the interplay of a number of factors that are yet to be studied. The fact that a large majority of eyes undergo such changes to an extent that makes them of practical importance makes it imperative that the astigmia shall be remeasured whenever symptoms arise that may be due to uncorrected astigmia.

HYPERMETROPIA RESPONSIBLE FOR HETEROPHORIA ASTIGMATISM AND MYOPIA.

S. M. Payne, M. D.

NEW YORK.

This paper contains an explanation and argument based upon statistics of the relative frequency of these different conditions at different ages. It was read before the American Ophthalmological Society, July 10th, 1918.

In the year 1888 the Stevens theories and claims of cures of certain ailments by partial tenotomies caused so much interest that a committee of ophthalmologists and neurologists was appointed to investigate them. In the writer's belief, the results of the new treatment were not satisfactory, but it was adopted by a large number of ophthalmologists all over the country. They were divided into the following six groups as to cause of deviation: muscles too strong, too weak, too long, too short, attached too near the cornea, and malformation of the orbit. Stevens, in his book on Functional Nervous Diseases, states that the superior rectus of one eye is too strong, or the inferior rectus of its fellow is too strong. In either case he calls the vertical tendency "hyperphoria," and cuts the superior rectus of the eye that is on the higher plane. If that fails to correct the tendency, he cuts the inferior rectus of the fellow-eye.

During the investigation by the committee the writer had the good fortune to measure the tendency before and after these operations. During the first period of the operations the writer discovered that the eye operated on was the fixing eye, and, of course, was the eye on the horizontal plane, while its fellow was below it. A commonsense view afforded a simple explanation. Instinctively, man or animal fixes with the better eye, whether or not the fellow-eye has a tendency to deviate. The writer saw cases of tenotomy of superior rectus in eyes with vision 20/20 to 20/15, while the vision of their fellows was 20/30 or 20/40 or even less, this faulty vision being due to a greater error of refraction. Thoroly convinced that the vertical tendency to deviate was due to the difference in the error of refraction, and that the tendency was downward, the writer worked out the causes and discovered that the fault was not in the muscles but in errors of refraction. Those muscles act instinctively to aid the fixing eye by a greater muscular effort, just as an eye with distorting vision produced by lesion causes the eye instinctively to turn. If the fixing eye is better than the two combined, the affected one is discarded.

On this subject a paper was written and read before the ophthalmic section of the Academy of Medicine in 1893, with a report of 200 cases showing the following:

Refraction the same:			
Esophoria	70		(90.1 per cent.)
Exophoria	21		
	—	91	
Hypophoria	1		
Hypoesophoria	5		(9.9 per cent.)
Hypoexophoria	4		
	—	10	
		101	
Refraction different:			
Horizontal tendency	19		(19.2 per cent.)
Vertical tendency..	80		(80.8 per cent.)
	—		
	99		
Tendency downward	65		(81.25 per cent.)
Tendency upward..	15		(18.75 per cent.)
	—		
	80		

TORSION.

After reading Dr. Savage's paper on Insufficiency of the Oblique Muscles, the writer began to look for cases showing those defects, and found only three, all of which were in eyes having a different error of refraction. This led the writer to prepare and read a second paper before the ophthalmic section in 1898. In this collection of

514 cases the following conditions appeared:

Refraction the same:		
Horizontal tendency....	194	(81 per cent.)
Vertical tendency.....	45	(18 per cent.)
	239	
Refraction different:		
Horizontal tendency....	42	(14.55 per cent.)
Vertical tendency.....	233	(85.45 per cent.)
	275	
Hyperphoria	74	(31 + per cent.)
Hypophoria	159	(68 + per cent.)
	233	

Of these two papers combined, 340 showed the same error of refraction, the tendency to deviate being confined to the horizontal plane, 83.82 per cent., and those showing a vertical tendency, 16.18 per cent.

The remaining 374 cases were anisometropic, showing a horizontal tendency to deviate of 16.32 per cent., and a vertical tendency of 83.68 per cent.

It thus appears that the totals in the two classes of cases are virtually reversed, the percentage being about 84 and 16 per cent. respectively in each class, the difference being about one-seventh of 1 per cent.

The third paper on this subject was published in 1904, in the Archives of Ophthalmology, vol. xxxiii, with a report of only a dozen cases.

EMMETROPIA.

The writer believes that all the external ocular muscles supplied by the third nerve act with the ciliary muscle in accommodation. The four recti muscles are so attached to the globe of the eye that, acting singly, they turn in the direction of that muscle. Any two muscles acting together turn the eyeball in the diagonal of these directions, as in looking around a room. The oblique muscles rotate the eyeball on its anteroposterior axis, keeping the eye in its vertical plane.

The internus and inferior rectus are governed by a common tendon,—the ligament of Zinn,—which is attached around the circumference of the optic foramen except at its upper and outer part. These two muscles are larger and stronger than any other two muscles combined, the internus being the larger and stronger. In accommodation they act together, of course, downward and inward. The superior recti are the thinnest and narrowest of the four recti muscles which pull the eye upward and inward. The inferior obliques, thin, narrow muscles, pull the eye upward and outward, and both are supplied by the third nerve. If the inferior oblique turns the eye outward above to keep it on its vertical plane in accommodation, what action could the superior rectus take except to relax? It is hardly logical to assume that it is the only idle muscle in accommodation supplied by the third nerve. It must be included in the process of accommodation, the superior rectus and inferior obliques counteracting or counterbalancing each other, and holding the upper part of the eye in its original position, while the internus and inferior rectus turn it inward and downward. At the same time the externus and superior oblique relax, so as to place the lower part of the eye directly under the upper part, thus keeping the eye in its vertical plane, turning downward and inward.

When hypermetropia is the same in both eyes, and the vision is normal, the tendency to converge is equal in the two eyes. If esotropia develops, one eye turns downward and inward by increased action of the two muscles to avoid diplopia. We should call this a voluntary contraction, because it is independent of the amount of stress necessary to work with the fellow-eye. That this is independent of the action necessary for accommodation is shown by the fact that there is usually no latent hypermetropia. That is, the eye would accept a +4 D., while the fixing eye would probably have a manifest of not more than 1 D. When under atropin they would both accept +4 D. When they work together (absence of squint), the manifest varies from nothing to probably the full amount of error. When the hypermetropia is different, we have either hypophoria or hypoesophoria, more often the latter. The hypophoria is in the more hypermetropic eye, while the fixing eye is on the horizontal plane.

When hypermetropia differs in the two eyes, and each accommodates to correct its error, the eye with the greater error turns more inward, as it turns more downward and may be thrown on a different plane. Torsion is more apt to be found in myopic eyes differing in refraction. As they cannot work together, the discarded eye is turned outward and downward by the contraction of the externus and superior oblique.

PSEUDO- AND TRUE HETEROPHORIA.

Dr. Savage claims that pseudoheterophoria is the amount that glasses can correct; that true heterophoria is the uncorrected esophoria in hypermetropia, the uncorrected exophoria in myopia, exophoria in hypermetropia, and esophoria in myopia. If it can be shown that what Dr. Savage calls "true" is pseudoheterophoria, something worth while has been gained. Our literature on the subject of accommodation is with emmetropic eyes or eyes made emmetropic by correcting glasses. This is preliminary to what we wish to prove. We will take 13 inches as a comfortable distance for an emmetropic eye. The first impulse is to see distinctly, causing the crystalline lens to increase 3 D. The second impulse is to avoid diplopia by converging to a point at 13 inches. So long as nature provides an emmetropic eye to go with accommodation and convergence to a given point, all goes well. But when eyes hyperopic 3 D. have to accommodate 6 D., an attempt to converge to a point 13 inches away, when the natural convergence would be six and a half inches, all goes wrong. This convergence to 6½ inches is prevented by a volunteer contraction of the externi and superior obliques—the counteraction muscles; unless it is possible for the interni and inferior recti to contract, only half the amount of the ciliary muscle. In such cases, if we do not get a convergent squint, we have either esophoria or exophoria. The cases of exophoria in hypermetropia can be attributed to two causes, working together or separately:

1. The strain or fatigue of the ciliary muscle may come first, which would be indicated by a blurring or, as patients often say, everything turns black before their eyes. This would be followed by a relaxation of the internal and inferior recti muscles.

2. The fatigue in convergence is more likely to come first, as they are antagonized by two opposing sets of muscles, the externi and the superior obliques, to offset the extra physiologic action of the interni in accommodation to a given point, indicated by the extra increased curvature of the crystalline lenses. The indication of the interni fatigue is either a separation of the letters into two sets of letters, or a tendency to do so, indicated by the broadening out of each letter, making the letters unrecognizable. This condition is described by the patient as "the letters dancing all over the page." This may mean either exophoria or esophoria, or alternating struggles against the ciliary muscles to hold convergence at a distance of 3 D. We may have exophoria for the near and esophoria for the distance, which is not at all uncommon, and in other cases exophoria for both far and near, which is often found.

When the hypermetropia is different, the eye with the greater error moves inward and downward, on account of greater muscular effort to correct the difference. Thus hypoesophoria 80 per cent. The hyperesophoria of 20 per cent. is accounted for by the internus and inferior rectus becoming tired, for the same reason that we have exophoria in hypermetropic eyes the same.

If the full correction for the hypermetropia is made, Dr. Savage's true heterophoria turns out to be the pseudoheterophoria. When this full correction is given, the interni and ciliary muscles act in harmony; and neither the exophoria or hypoexophoria any longer exists either near or at the distance. Recently, considerable attention has been given to ciliary muscle fatigue by some of our distinguished ophthalmologists. The most recent was by the chairman of a committee of the ophthalmic section of the American Medical Association for eye

muscle research. This report on the ciliary muscle gave the measurement of fatigue at different ages.

While such reports are interesting, their practical value is questionable. If all errors of refraction are corrected, ciliary muscle fatigue will be confined practically to emmetropic presbyopic eyes, and to those of younger people who hold their work too near the eyes. It is the opinion of some ophthalmologists that amblyopia, in hypermetropia, precedes the squint, and of others that amblyopia comes subsequent to the squint from the non-use of the eye. As this paper is confined strictly to muscles and refraction, no other amblyopic cases are considered.

In the writer's opinion, excessive accommodation causes double vision, followed by alternating squint, which later on becomes a permanent squint of one eye. While the writer agrees with the latter group that the amblyopia is subsequent to the squint, he does not believe that it is directly due to the squint. We have all seen eyes where the squint had existed for years with normal vision in the squinting eye, with or without a glass. The reason for this is that the accommodation in that eye has continued, and all rays of light have fallen upon the retina, including the macula, with the same sharp focus as that of the fellow-eye. This continued sharp focus keeps the retina active, notwithstanding images are ignored or suppressed. When we find a squint of long standing with amblyopia, we find the hypermetropia to be 4 D. or over, with absolutely no accommodation. This produces the amblyopia, because the rays of light fall upon the retina and macula under circles of diffusion. With no focus to stimulate the retina, the eye becomes amblyopic. This eye will show under the test the total error, while its fellow will show about one-fourth. If the two eyes are placed under atropin, we shall probably find that the fixing eye has the same amount of error, with no increase in the refraction of the squinting eye. We have also noticed that very high degrees of hypermetropia, such as 6 or 7 D., do not have squint. Such cases we shall find are amblyopic unless glasses have been worn to correct the error.

ESOPHORIA IN MYOPIA.

Esophoria in myopia is not very common and is found when myopia is the same in both eyes. In these cases we have no accommodation or less than the amount required to stimulate convergence to the point of fixation. The interni take on an independent contraction to produce sufficient convergence to prevent crossed diplopia. A forced action of an individual muscle outside the laws of accommodation and associated movements of the eyes may produce heterophoria, and in the case of myopia produce esophoria. The myopia corrected will force the eyes to accommodate, as in emmetropia, and the convergence produced by the action of the ciliary muscle will correct the esophoria. When the eyes cease to maintain binocular single vision, for the want of a stimulating influence of the ciliary muscle, one eye begets a tendency to diverge and soon becomes more near-sighted. It then begins to turn outward and downward. When the prism test is made to determine the amount of deviation, the eye will move further outward or downward to avoid fusing with the other light. When the externus and superior oblique can no longer overcome the prisms, they give up, and the larger light crosses to the other side and may move above or below and back again to the right or left. It seems that any of the six muscles are liable to come into play to avoid fusing. When these muscles become exhausted in their efforts and the lights are finally brought together, the eyes see a smaller and a more defined light in the larger and more blurred light. Unless the vision is very faulty under the correction, the eyes will work together when the image is made the same size on the retina, even in cases of actual divergence, and even after partial tenotomies, when the muscles are not displaced by the cutting.

While the cases above reported show about 84 per cent. horizontal tendency, when the refraction is the same, and

about 84 per cent. vertical tendency in anisometropia, about 20 per cent. of the 84 per cent. are hyperphoria and 80 per cent. hypophoria. The cases where refraction is the same show 20 per cent. exophoria in hypermetropia and about 20 per cent. esophoria in myopia; so the exceptions to the rule are about the same.

REGULAR ASTIGMATISM.

During the year 1892 the writer adopted the theory that the greater curvature of the cornea is in the horizontal instead of the vertical axis in more than 50 per cent. of the cases after the age of fifty years.

A paper was subsequently prepared and read at the ophthalmic section of the New York Academy of Medicine in 1894. The following is a summary of the 1071 cases therein referred to, grouping those, according to age, in the horizontal axis. Age ten up, 27 per cent.; twenty up, 29 per cent.; thirty up, 34.4 per cent.; forty up, 47 per cent.; forty-five up, 49.3 per cent.; fifty up, 54.4 per cent.; sixty up, 64.3 per cent.; seventy up, 100 per cent.

It was observed that oblique axes increased with age below axes 45 and 135, but those cases were not included. No case of astigmatism was found in children under six years of age, and only about a dozen in children under ten. These were excluded.

At the beginning of the writer's studies the text-books stated that astigmatism was either congenital or acquired. When the theory that the axis in the greater curvature of the cornea changed with age was adopted, a cognate idea was presented; it was observed that in the majority of cases the defect was acquired and that the cases of a high degree were congenital and probably the only ones.

Among the thousands of cases examined, from which the 1071 were selected, no cases of congenital origin were discovered. Still the congenital theory was so widely held among eminent specialists that the writer hesitated to publish his convictions. But an added experience of a quarter of a century has dissolved all doubt. Ophthalmologists agree that, as a rule, babies at birth are hypermetropic; and, as they grow, the eyes become more nearly spheric until the majority become round or emmetropic. Add to this the fact that no cases of astigmatism are found under the age of six in the former list of 1071 cases, or the present list of 1752, we are forced to the conclusion that astigmatism begins at the kindergarten age, say from six to ten, due to hypermetropia, at a time when near eye-work is very light.

Assuming that the primary cause of astigmatism is hypermetropia, we proceed to consider the unsettled question, "How is astigmatism produced?" The distinguished writers Fuchs, Juler, Donders, and Schmidt-Rimpler locate the seat of astigmatism in the cornea. Landolt says it is occasionally formed by the crystalline lens. Fuchs, Landolt, and others speak of astigmatism as congenital or acquired, either from irregular development or an irregular action of the eye. They all state that the greater curvature of the cornea lies closer to the vertical meridian than to the horizontal. When they say it is congenital, there is no more to be said; when they say it is acquired, some of them speak of the lids as the cause. They also speak of an increased curvature of the crystalline lens in the opposite axis to the greater curvature of the cornea, to correct the corneal astigmatism entirely in some cases and in others overcorrect it, as Landolt mentions and claims to have proved by the use of atropin.

That the crystalline lens becomes astigmatic in order to correct the corneal astigmatism is, we believe, universally accepted, but we are not aware that any one believes the crystalline lens produces it when there is no corneal astigmatism. The crystalline astigmatism is only a remedy for the corneal astigmatism.

The purpose of the lids in astigmatic cases is to cut off the end rays on the macula, so as to square the letters and make them more readable. The lids also trombone in myopia and high degrees of hypermetropia in order to cut off a part of the rays to diminish the

circles of diffusion. When these three classes of cases are corrected with glasses, the lids cease to trombone and furnish no evidence of having produced astigmatism. If the lids produce permanent astigmatism, this pressure would come directly above and below the cornea, thus making the vertical curvature greater. If this pressure were continuous, we might have some reason for believing that the lids cause astigmatism, partly closing to produce vision, if only for a moment.

The writer has endeavored to eliminate the three universally accepted causes of astigmatism in order to bring forward what he believes to be the true cause, namely, the external ocular muscles. The six are all opposing muscles, and all work together in accommodation. We begin life with hypermetropic eyes. A child's mental capacity at first is not strong enough to fix intently on any object, so no direct image is formed on the retina. When he gets away from his mother's lap and learns to walk, his mind is still not sufficiently developed to form a sharp focus on objects. This weakness may produce convergent squint, though not astigmatism, as the eyes are not fixed long enough on objects, and then they are constantly changing to distant objects.

When children reach the kindergarten age, as the hours are short and the study is light, only a few cases of astigmatism develop. Only 20 plus and 9 minus were found—a total of 29 of the 1752. During the school years from ten to twenty more concentration is required and longer hours, and astigmatism is increased to 82 plus and 58 minus, total, 140. From twenty to thirty, when a large percentage have entered the commercial world, and some are still in college, the work is harder, with longer hours. The number in this decade is 218 plus and 143 minus, total, 361. In the thirties the work is still more trying, as it is the time entirely of practical application of the knowledge they acquire in the second and third decades. The number is increased to 277 plus and 185 minus, total, 462. In the forties we find a slight decrease, to 230 plus and 146 minus, total, 376. This is accounted for by half of the fifth decade being in the presbyopic age. In this period we find the increased vertical curvature of the cornea decreased 11.6 per cent., while the obliques above axis 45 degrees and 135 degrees, including axis 90 degrees, decreased only 7 per cent. This means either that the axis is shifting from the vertical to the oblique above axis 45 degrees and 135 degrees, then later below and finally to the horizontal, or that the astigmatism disappears first in axis 90 degrees and second above the 45 degrees, and later on in life there is a decrease below axis 45 degrees until the astigmatism is almost entirely confined to axis 180 degrees for plus glass, and 90 degrees for minus glass.

If we are willing to admit that the four external ocular muscles supplied by the third nerve act in accommodation and the fourth and sixth nerves supplying superior oblique and external muscles counteract at the time of accommodation, then we are obliged to acknowledge that all these muscles act in correcting hypermetropia at the distance.

These muscles are inserted in the sclera near the cornea in such a way that any one muscle may have more or less a countereffect upon any other muscle, unless it should be the interni and inferior recti, which are from the same origin; still, in a way, they oppose each other as they pull downward and inward instead of directly downward or inward. The superior recti guide the inner and upper direction of the eyes to prevent them from being too much under control of the inferior recti. The inferior oblique acts in accommodation to counteract the superior recti and keeps the upper part of the eye in the vertical plane, just as it would be when at rest. The superior oblique relaxes to allow the inferior rectus to hold the eye below in its vertical plane, while the eye is turning downward and inward. In this particular action the superior and inferior obliques are allies, because the relaxation of the superior oblique would not

be sufficient if the inferior oblique did not prevent the eye from tipping inward above. On the other hand, the upward action of the inferior oblique can prevent too much torsion by the relaxation of the superior oblique. All these actions are to prevent torsion. Besides these, we have the direct opposing actions, the superior oblique against the superior recti, inferior oblique against the inferior recti, and externi against the interni, which is shown by paralysis of any single muscle, as the eye turns from that muscle in the direction of the opposite muscle.

We must keep in mind that hypermetropia is corrected from the time the eyes are opened in the morning until closed at night by accommodation for the distance, except in high degrees, when the eyes frequently blur to give the muscles a rest. Another exception is when the hypermetropia is so great that all attempts to correct it are abandoned. These cases become amblyopic. This hypermetropia runs from 5 D. to 7 D., and in some cases more, and vision is usually 20/100 or 20/70.

We have another class of amblyopia: compound hyperopic astigmatism about equally divided between the sphere and cylinder, total, 5, 6, or 7 D. These cases, in my opinion, struggle to correct the error, change half the error into astigmatism, without being able to accommodate to correct the remaining spheric part. This gives a double lined diffusion instead of circle diffusion. (The writer's explanation in his paper, published in 1894, on the changed spheric cornea to spherocylindric by the action of the muscles, will be the same here, as time has not changed his opinion.)

Our experience in taking the tension of an eye with the fingers shows us how easily the curvature of the eyeball is increased between two fingers. Why should not the curvature of the eyeball be increased by two opposing muscles? In fact, the insertion of these muscles is practically where the fingers are placed in taking the tension. If the pulling of the opposing muscles can have a like effect as the fingers, we not only have an increased curvature of the eyeball but of the cornea as well. As the eye approaches the presbyopic age the ciliary muscle has less effect on the eyeball, as it is gradually less soft and less yielding to the opposing muscles. Thus, the accommodation begins to subside and the astigmatic error changes into a spheric error. Many of the writer's private cases have demonstrated this fact.

The writer has collected an additional list of 1221 cases from his office records, which afford further proof that muscles cause astigmatism. In compound hypermetropic astigmatism, when the sphere is the same, we have corresponding axes in the astigmatism. The table shows this to be true in 90.4 per cent. against 9.6 per cent. different axes; also that the axes differ when the spheres differ. These cases show only 25 per cent. corresponding and 75 per cent. different axes. This proof holds good with both compound myopic and simple astigmatism; also in mixed, when spherocylindric glasses are ordered the same or different.

We sometimes overcorrect the astigmatism at the expense of the spheric or the reverse, as the eye may see the same with a slight overcorrection of the other, but to increase one without diminishing the other reduces the vision. If this be true, the theory advanced may be wholly true. The reason as it looks to the writer is this: The same sphere requires the same accommodation which causes a corresponding axis. Anisometropia, requiring more accommodation in one eye than in the other, causes a torsion of that eye which makes a different axis; or if the accommodation is suspended in that eye, a torsion with axis different ensues on the reverse side.

In other papers the writer has stated that when astigmatism exists, whether the same, different, or only in one eye, the hypermetropia, if any, will be found to be the same, with few exceptions. The usual exceptions occur when there is a decided difference from 1 D. to 4 or 5 D. This is true also with no astigmatism. Only 3 cases were found in 19 that had less than 1 D.

difference in simple hypermetropia. With astigmatism only 5 in 17 cases with less than 1 D. spheric difference. Total of 36 cases, 28 more and 8 less than 1 D. difference, 78 per cent. and 22 per cent. The apparent reason for this is that if astigmatism develops in anisometropia, it begins first in the eye of the greater hypermetropia by changing the difference into astigmatism, making the spheric part the same. If astigmatism is brought about by excessive accommodation, it comes first in the eye with the greater error, as it requires more effort to correct this eye by trying to equalize the vision of the two eyes. This fails when the difference is too great. That is why we seldom see the difference less than 1 D. If any further astigmatism develops, it is the same in both eyes, leaving the spheric error still the same.

Among 23 con. squint cases, all those found under the age of six were spheric only. The only astigmatic cases were ages ten and eleven. These cases were straightened by prescribing the ophthalmoscopic measurement, and verified with the test-lenses in only the two astigmatic cases. Only in one was atropin used, and that was in the astigmatic case aged eleven. The only other case above the age of the two astigmatic cases was aged sixteen, which may have been tested with the lenses; but, as it was not an astigmatic case, +4 D. was ordered, as found by the ophthalmoscope. The other 20 ages ranged from nine years down to twenty-two months.

In looking over the anisometropic eyes and same spheric error to see what influence each had on the axis of the astigmatism, the same books were examined, and the cases with no astigmatism were copied to get the percentage of same sphere and different. The result follows:

Spherical, same, 1,433 cases.....97½%
Spherical, different, 38 cases..... 2½%
Spherocylinder. same, 372 cases.....94 %
Spherocylinder, different, 26 cases.... 6 %

In conclusion the writer restates what he has attempted to prove by the several groups of cases in the present findings of 2,974 astigmatic and 1,818 spheric cases—4,792.

First: Astigmatism is not congenital, not acquired by the crystalline lens, and not by the action of the lids; because none of them would start the greater curvature of the cornea in the vertical axis at 100 per cent. under age ten and gradually change the axis of the greater curvature 100 per cent. in the horizontal axis at the age of seventy. This evolution is complete at the end of the ciliary muscle action. After this age, when the ciliary muscle has ceased to accommodate, the external muscle cannot assist in accommodation, but acts only in convergence and in associated movements.

Second: The axis of astigmatism is largely controlled by the sphere; that is, the axis corresponds when the sphere is the same and differs when the sphere is different. In the latter case we may find torsion, but not when the sphere is the same. The exception to this rule is small.

CAUSE OF MYOPIA.

It is an accepted fact that hypermetropic eyes become round or nearly round at full growth, and in some cases myopic. In myopia the increase in the anteroposterior diameter is thought to be due to the thinning of the sclera posteriorly. This has been demonstrated by microscopic examination on sections of the sclera, as well as by our ophthalmoscopic findings. The writer believes that this posterior thinning begins in the advanced stages of myopia, due to a tendency to diverge, with a more rapid increase in actual divergence. In low degrees of myopia the fundus usually looks normal, and we seldom see posterior staphyloma in eyes of less than 8 D. The sclera when normal is thicker posteriorly and gradually becomes thinner as it approaches the cornea, so the thinnest part is anterior to the insertion of the six muscles. It is quite probable that the constant correcting of hypermetropia in children is not entirely by the ciliary muscles, but is aided by the six external ocular muscles attached to the sclera at a corresponding distance from

the cornea. It seems reasonable to suppose that these muscles just back of the thinnest part of the sclera would depress that part of the sclera including the cornea, producing in a measure conical cornea; that is, a deeper anterior chamber. Hypermetropic eyes that develop into emmetropic at maturity may be due to this muscle action, or at least influenced by it. Children who are obliged to hold their book at 8 inches or less to see the print increase the accommodation 5 D. on probably 4 or 5 D. distant error. This great strain to correct 10 D. may start a low grade of sclerochoroiditis which may be the starting-point of myopia. Those of hereditary tendency are more easily influenced. This thinning of the sclera is occasionally indicated by a choroidal ring about equal distance from the insertion of the muscles and the cornea.

CONSERVATIVE TREATMENT OF ASTHENOPIA IN CHILDREN.*

EDWARD R. WILLIAMS, M. D.

BOSTON.

During a five years' study of refractive conditions among our school children, the need of conservative treatment seemed to me most important. Unfortunately, it is a subject which has been somewhat neglected and considered decidedly uninteresting. Both public and private school pupils were treated. A more or less successful attempt was made to keep in touch with these pupils by yearly examinations, watching constantly for any new complications. Office methods were copied in the hospital clinic, as closely as conditions allowed.

Considerable extra time and pains were taken to give hospital patients as good advice and treatment as possible. Palliative treatment cannot be carried out quickly; it is not possible to dispose of all cases in one or two visits. It requires, first of all, a careful assembling of data in order that an exact diagnosis can be made. To understand the complaint of the child it is quite essential to consult with the parent or the school nurse. Only in this way can we decide, in doubtful cases, whether glasses are necessary or whether some other better alternative treatment will bring the desired result.

The children were divided into three groups—

Group 1. Pupils usually brought by the school nurse. who had high refractive errors requiring immediate correction with glasses.

Group 2. Scholars having a small—less than one-half diopter—refractive error, with defective vision of one eye; who sometimes complain of indefinite symptoms, and who very often require glasses as well as general medical treatment.

Group 3. Children brought to the clinic or office by the parent very often present more difficult problems. Frequently such children are brought for an eye examination not because their vision was found defective, but on account of some slight eye symptoms which suggested eye-strain.

Group 1. These children need glasses prescribed immediately in order to preserve vision from getting any worse; also to prevent strabismus. Only by this means can they progress steadily with their education.

*Read before the American Ophthalmological Society, July 10th, 1918.

Group 2. About 75% of all the scholars of this kind require glasses to relieve very definite symptoms of asthenopia. A majority should receive a combined treatment to relieve the eyes and other obvious defects; as adenoids, diseased tonsils, decayed teeth, etc. About 20% of this group never received glasses.

Group 3. This includes children generally brought to the clinic by the mother. They may or may not have been notified that the patient had failed to pass the school test. Very often the pupil comes because the parent has observed that headaches start after studying.

Conservative or palliative treatment can be only properly undertaken when careful tests show the following conditions exist:

A. A very small refractive error carefully determined under a mydriatic. A comparative test was always made without drops. In my office two independent estimations of the refraction were made, but in the clinic the retinoscopy was generally not attempted without drops, as it takes too long, and our inexperienced house-officers have rarely had an opportunity to try this procedure.

B. The original test of vision, let us say, disclosed a decrease of one eye only. It was reduced to 20/40 at least, in order to attract the teacher's attention. The school tests usually were found correct. My own tests tended towards a slightly higher average because they were more carefully done under a little better conditions.

C. Examinations by the medical or throat consultants at the hospital showed other physical ailments, such as malnutrition, indigestion with constipation, bad teeth, diseased tonsils, and adenoids. Concerning these complications among private cases, it was necessary to get the data from the family physician.

Conservative treatment is justified if we admit that a temporary lowering of vision may accompany the different milder types of chronic conjunctivitis or even hyperemia of the conjunctiva. If persistent conjunctivitis is cured with drops, the vision improves and the child may then be able to pass the required visual examination.

This axiom has been one of my guides in the treatment of many children. It is so simple, and at the same time so effective, that often the child requires no further treatment. It seems to me that it should be tried in a great many more cases, but I know that few of my colleagues will agree. The reverse principle has guided most ophthalmologists that, having brought corrected vision to normal with proper glasses, all other ocular complaints would cease. A few of our members will agree that special emphasis should be laid on a principle of conservative treatment, which is directly antagonistic to the views of the majority. It is based on the broad, common-sense idea that glasses for many an average child, of the special group we are considering, should not be the one and only treatment. General practitioners outside of certain larger cities have been guided by this principle. The possibility that these doctors might do harm to the pupils' eyes by ignoring dangerous asthenopic symptoms has been eliminated by the ease with which oculists of nearby smaller towns can be consulted.

Special care was taken to separate the backward scholars in order to give them particular advice. If a child is in its proper grade at school and complains of indefinite asthenopic symptoms, conservative treatment is indicated. A much more thoro search for the underlying cause of complaint must be made, however, if the child is two or more grades behind the average. It makes no great difference if the scholar is one grade behind the average. A large proportion of public school children finish their education upon graduating from the grammar school. Several reasons, aside from physical defects, may explain why they are apparently backward, the most important of which are:

A late start, when almost 7 years old.

A change of residence with a consequent change of school and a readjustment into a different class.

Sickness in previous years, but which had left no bad sequelae to affect the scholar's subsequent progress.

On this account, I divided all the children into two groups:

Group A. Pupils in proper grade or one grade behind. (84%.)

Group B. Pupils two or more grades behind. (14%.)

If a scholar is in Group B, it is the duty of the physician to work with the educators to eliminate as rapidly as possible all physical defects. By so doing a determined effort is made to promote the child to a higher class or at least keep it from falling any further behind. The experience of one of our school nurses is that if a scholar once falls behind, an advancement into a higher class is next to impossible. The best that she expected was to report that the child was holding its own without further complaint, if all medical treatment was carried out faithfully.

Our aim is to improve both the vision and the general ability of the scholar to continue its studies by removing any evident physical defect. Palliative treatment means, of course, that a larger proportion do not receive glasses than in either of the other two groups. This method is used working on the assumption that so-called eyestrain can sometimes be treated by a combination of general medical treatment and the cure of conjunctival irritation by suitable collyria.

A moderate degree of chronic conjunctivitis often proves the most important cause of asthenopia. Also a conjunctival irritation, by causing the pupil to think about his eyes, will sometimes disclose a chain of symptoms which have no apparent relation to the eyes. For example, the child complains of the eye aching. This is often described as a headache. This does not always prove to be a characteristic frontal headache, because small children very often cannot describe accurately this symptom without some further questioning by the doctor. Hemicrania or pain in the eyes seems often the same thing to the patient. To differentiate between the two complaints we must wait until a careful refractive examination has been made before we decide if headache is likely to result from a very small refractive or muscular error.

Let us suppose the pupil complains of a frontal headache with intermittent attacks of pain and tenderness of the eye-balls. This starts two or three hours after the noon meal, at about the time school closes. The headache seems to come after studying. A careful refractive examination is made without coming to any definite conclusion. The diet is investigated and we discover that constipation and intestinal toxemia have caused the headaches. The medical consultant treats these conditions and the general health of the patient promptly improves. In the meantime, soothing collyria having been prescribed, we find often a perceptible improvement of vision. If the first visual test proves the child unable to meet the State requirement, the above treatment will remedy the defect. Mental dullness changes to alertness after freeing the intestines of a number of poisons. At the same time, by relieving conjunctivitis, the child's attention is withdrawn from his eyes and it proceeds with all studies in a normal manner without further complaint.

If we have found only insignificant physical or ocular defects present, we can now consider a very interesting mental attitude of some scholars towards apparent asthenopia. We realize how easily suggestion will affect a cure of the childish mind. A resignation to the inevitable will also stop all complaints. This is shown very well by observations made by one of the teachers at a large boarding-school for girls in this state. A certain number of the pupils complained of headache and other asthenopic symptoms and were sent me for examination. For some of the girls glasses were prescribed, and they started again with their studies.

It was a rule that only the senior class could study in their rooms, an arrangement much envied by

their younger schoolmates. The lower classes all gathered together to study, under the supervision of a teacher, in a large hall. The girls claimed the illumination of this hall was insufficient and that it was a frequent cause of the asthenopia. Most of the younger scholars, for whom glasses had been prescribed, soon became resigned to working under the above conditions and ceased fretting. Also it was noticed that they very often discarded their glasses and made no further complaints. We must acknowledge that any child is liable to act in just this manner.

Unless strict supervision by their elders is observed, the child may take off his glasses, especially in cases where hyperopic errors have caused the headache. The vision without glasses being very good, although possibly not perfect, and the headache stopped, the scholar will often experiment to see if he cannot get along without them. The oculist is deluded by thinking that his patient is carrying out his instructions. The ability of the pupil to reestablish his equilibrium, so to speak, has been ignored. In these cases glasses should not have been prescribed except as a last resort in case all so-called temporary asthenopia could not be relieved by using collyria, or, more often, some general medical treatment.

The need of giving a plus glass to a child to correct temporary accommodation weakness seldom arises. A series of experiments made upon both youths and adults convalescing from pneumonia and typhoid — these diseases chosen on account of the great drain on the patient's vitality—showed a wonderfully quick recovery of the accommodation. Tested one or two days after the crisis of the fever had been passed, the accommodation was generally reduced to one-half of normal. This reduction was in direct ratio to the patient's youth. Within two weeks the accommodation was again normal. Debility following such serious diseases, however, makes the child complain of eye-strain even from very small refractive errors.

The need of giving temporary relief with glasses should not be overlooked. This method of treatment is, of course, very generally employed. What is overlooked, however, is a decided tendency of a child to put aside the glasses as soon as symptoms cease, or anyway as quickly as experiment shows that no symptoms recur if the glasses are discarded during study hours. As mentioned before, this childish act is inevitable, and certainly very often it does no harm. During convalescence from some of the children's diseases—especially measles—the skillful prescribing of suitable collyria will suffice. At such times the child's complaints are apt to be more specific, and we must not fail to give every help to tide the scholar over a difficult period. The length of time that help with glasses or other treatment is needed varies in direct proportion to the child's recuperative power. A neurotic temperament is a complication which prolongs the treatment.

A few scholars are brought by the nurse or mother on account of apparent poor vision of one or both eyes. The failure of the pupil to pass the school tests may be due to shyness or nervousness, or to improper illumination of the test letters. Sometimes my tests did not confirm the previous ones. With such scholars it is often extremely important for the parent to report the actions of the child at home. Attention should be directed to any of the following characteristics:

a. Lack of concentration and good application;

b. Missing entire words or mispronouncing words when reading aloud;

c. A tendency to hold the book too close—simulating myopia.

d. Bad sitting posture;

e. Eyes or lids inflamed;

f. Too rapid appearance of fatigue, causing listlessness or inattention.

A temporary decrease of accommodation may follow very vigorous exercises, like football or rowing. Experiments to demonstrate such a condition have been recently begun, and in the future I shall hope to have more information to report.

A small decrease of vision always accompanies the lessened accommodation. This condition is presumably responsible for a good deal of the lack of concentration and inability to do good work during study hours at home in preparing home lessons. Such an artificially produced accommodation fatigue of a child may be compared to the easily demonstrated tiring of adult eyes after a busy day. These tests are especially hard to perform, because the child soon lacks interest and then does not make the maximum effort required. The best method seems to be to take a very small number of children and train them sufficiently to observe slight changes of visual acuity. If a series of tests made in the evening show a decrease, control examinations the following morning are necessary. My own observations have proved that my accuracy of observation was influenced often by mental conditions. If the mind is dulled by loss of sleep, nervous fatigue, etc., the test becomes proportionately more difficult. Brain fatigue more often caused a decrease of accommodation than physical exercise.

SOME OBSERVATIONS ON ASTIGMATISM.

JOHN GREEN, JR., M. D., AND WILLIAM F. HARDY, M. D.

ST. LOUIS, MO.

Remarks on the terminology of astigmatism especially direct and inverse, and on the frequency of the latter, with discussion of practical points in dealing with astigmatism. With three charts. Read before the American Academy of Ophthalmology and Oto-Laryngology, August 6th, 1918.

Astigmatism has generally been divided into direct, or astigmatism with the rule (meridian of greatest curvature vertical or nearly so), inverse, or astigmatism against the rule (meridian of greatest curvature horizontal or nearly so), and oblique astigmatism (meridian of greatest curvature in the vicinity of 45° or 135°). Some writers omit the third subdivision and classify these oblique astigmatisms with the first group. As we[1] have recently pointed out, this classification is purely arbitrary, as these cases might with equal reason be classified with astigmatism against the rule.

It is singular that an exact terminology has not been adopted for this most exact subdivision of ophthalmic science. One has only to peruse the chapters on refraction in our text books to learn that each writer has felt at liberty to make his own definitions, which are generally characterized by a vagueness incompatible with scientific precision. We note that even Jackson[2], whose careful study of changes in astigmatism is so illuminating, speaks of direct and inverse astigmatism with meridians of greatest curvature "approximately" vertical and horizontal.

In order to eliminate any uncertainty in the future as to what are the boundary lines of the three groups, we propose the following definitions:

Astigmatism with the rule, or direct astigmatism, shall include all cases with meridian of greatest curvature at any point on the arc from 46° to 134°.

Astigmatism against the rule, or inverse astigmatism, shall include all cases with meridian of greatest curvature at any point on the arc from 0 to 44° and from 136° to 180°.

Oblique astigmatism shall include all cases of astigmatism with meridian of greatest curvature exactly at 135° and 45°.

It has been argued that there is no necessity for any subdivision, for the reason that practically every eye possessing an astigmatic error should wear a cylindrical correction and that it is immaterial whether the meridian of greatest curvature is in the vicinity of 90° or 180°. Theoretically, this contention has merit. But we are convinced that it is useful, on clinical

grounds alone, to differentiate at least between direct and inverse astigmatism, for the reason that the latter presents certain features of special interest and importance.

Our study indicates that inverse astigmatism is more frequent than is generally surmised (in 1024 eyes with regular astigmatism we found 283, or 27.7%, inverse). Furthermore, as Theobald[3] has pointed out, an eye with this type of error is much more capable of "hiding it away" than is an eye with direct astigmatism. This observation accords with our own experience. We are convinced that prior to our systematic use of Lancaster's astigmatic charts many examples of low inverse astigmatism eluded us.

In our series, too, we determined by neutralization of spectacles prescribed by ophthalmologists who had preceded us that more than half of the men had failed to incorporate a cylinder to correct an inverse astigmatism. Glasses prescribed by refracting opticians only very rarely indicated any appreciation of the existence of this type of error. Low inverse astigmatism gives rise to especially annoying symptoms, such as headaches, blepharitis, congestion of the globe, etc. It is less well borne by the eye than an equal degree of perpendicular astigmatism.

One of the principal reasons for the greater degree of asthenopia in eyes with inverse astigmatism is the greater interference with the legibility of ordinary printed type. In direct astigmatism the vertical components of letters are distinct, whereas the opposite is the case in inverse astigmatism. Letters with vertical components distinct are more easily recognized than those with horizontal components distinct. One has only to render oneself artificially astigmatic with the rule and then artificially astigmatic against the rule (using the same cylinder) to appreciate the difference in distinctness of the same line of letters. This difference can also be beautifully demonstrated by the camera. In the illustration, the upper group of letters was photographed with an ordinary lens, the second group with a lens rendered astigmatic with the rule, and the third group with a lens rendered astigmatic against the rule (using the same cylinder). No one will fail to appreciate the lessened legibility of the third group. See Fig. 1.

It is probably an accurate statement of fact that one finds frequently that for which one is on the lookout. This is exemplified in the search for astigmatism, and particularly for inverse astigmatism. That we all possess some amount of astigmatism is a truism; whether it be corneal or lenticular is beside the point. Having detected a small amount of astigmatism against the rule, it does not follow that it should be corrected in all instances. In the treatment of this condition the exercise of judgment is as necessary as in all refractive work.

In the correction of refractive errors there are two things to be subserved, viz., improvement of vision and the increased comfort of the patient. If clarity of vision be gained without comfort, or comfort obtained with no improvement in vision, the result has fallen short of the ideal. The average patient will greatly prefer a correction which yields fairly good vision with perfect comfort to that which gives the most acute vision with an aggravation of his discomfort. And occasionally this is just the effect of incorporating a cylinder in the correction. We feel, therefore, that for some patients, especially elderly ones, who for years have been completely comfortable with spheres, it is ill advised to prescribe an astigmatic correction which, theoretically, is indicated. The confusion and discomfort incident to the new order of things offset any increase in visual acuity. Many of us are creatures of habits, and even of bad habits.

On the other hand, when it is definitely demonstrated that both vision and comfort are increased by an astigmatic correction, it is incumbent upon us to determine with all possible accuracy the strength and axis of the cylinder. And this may necessitate the use of cycloplegics in certain individuals above the age when such drugs are usually used. We believe this to be

good practice. We do not believe that a drug like homatropin ever produces glaucoma. It may precipitate an attack, but does not cause the disease. It goes without saying that a careful examination of the fundus, tension and field should precede the use of the cycloplegic in these cases. Hence the presbyopic patient need not be deprived of the advantages of a test under cycloplegia when the precycloplegic test has given unsatisfactory or conflicting results. It might appear superfluous to labor this point were it not for the fact that a large number of prominent oculists are unalterably opposed to the use of cycloplegics in adults of whatever age.

Fig. 1. Test letters photographed: The upper set with spherical lens giving images like those of the normal eye. The second set through cylindric lens imitating direct astigmatism. The bottom set thru cylindric lens imitating inverse astigmatism.

The advice of Clarke[4], that the full amount of astigmatism should be cor-

rected, cannot be followed in all cases with comfort to the patient. In numerous instances the postcyclopegic test reveals the fact that the patient is either made uncomfortable with the full cylinder or that the visual acuity is reduced. In either event a glass of less cylindric strength must be given. For instance, a plus 1.5 cyl. of a total of 2.5 may be all a patient will accept at the first test. Some time later plus 2 is accepted, and finally the full cylindrical correction is worn with comfort. It is not to be inferred that the astigmatism in such cases has changed. These facts have recently been emphasized by Col. Elliot[5].

One must be careful not to overcorrect an astigmatic error even in the slightest degree. It is better to err in the opposite direction. Wipper[6] has recently stated that a patient should be left with a quarter diopter of astigmatism with the rule uncorrected, as this is the normal condition and even essential for comfortable, if not perfect, vision.

Always a difficult problem is the management of cases of mixed astigmatism in which there is accommodative cramp. It is very disconcerting to prescribe a glass on the basis of a cycloplegic measurement, only to find that the patient complains bitterly of poor distant vision. Various measures, such as prolonged atropinization, rest of the eyes, change of occupation, sedatives, etc., often do not suffice to overcome the exalted tone of the ciliary muscle. It has seemed wise in some cases of this kind to yield to the demands of the patient for good distance acuity, by increasing the strength of the minus spherical element. We have not had cause to regret this departure from scientific accuracy.

Not rarely do we encounter cases in which one eye shows a low regular astigmatism, whereas the other eye presents a high degree. The cause for this discrepancy is often obscure. Without doubt a number of unilateral cases of high astigmatism are the result of trauma occurring at birth.

The following is an illustrative case:

In 1912 Baby, L. O., was seen by one of us four days after birth. The obstetrician stated that one blade of the forceps had pressed firmly over the child's left eye. The cornea was entirely opaque, but there were no inflammatory signs. Under dionin and hot applications, the cornea cleared.

A few days ago, this little girl, now six years old, was brought to us because the mother noticed that the child in looking at picture books had a tendency to close the left eye. Right vision 6/5. Left vision 6/40. The ophthalmometer showed: R. As. 1 mc, 90; L. As. 6 mc, 90. Both corneas were perfectly regular.

Oblique illumination showed the presence of three vertical striae situated in the deeper layers of the cornea, one coinciding with the inner pupillary margin, the second with the outer pupillary margin, the third midway between the latter and the outer limbus. A skiascopic examination disclosed a regular astigmatism plus 4.5 D with meridian of greatest curvature at 90°. With plus 4, cyl. axis 90°. V. 6/10.

Every one possesses a small amount of irregular astigmatism which is, of course, not perfectly correctable by any cylindrical lens. Whenever there is a deformation of the cornea from injury or inflammation, or when the lamellae of the lens are irregularly disposed or swollen, as in incipient cataract, there is bound to be more or less irregular astigmatism which may or may not be associated with the regular type.

In the presence of irregular astigmatism, whether of corneal or lenticular origin, it is thoroly worth while to determine with the greatest care the cylindrical or sphero-cylindrical combination which yields the highest vision. When the irregular astigmatism is a more or less fixed quantity, as, for example, in an eye with a cornea deformed by a long past keratitis or injury, a painstaking correction with sphero-cylinders will often be highly acceptable to the patient, who is grateful for the heightened acuity thus

secured. But every case is a law unto itself; not rarely a simple sphere, which yields less vision, is preferred to any combination.

An eye with an incipient cataract which has previously rejected all cylinders, may often be made to see very well with a sphero-cylindrical combination. But here again it is often a case of "Love's labor lost"—the combination is soon found uncomfortable or visually unsatisfactory. We presume that the explanation lies in the fact that the irregular lenticular astigmatism is constantly changing with the progress of opacification.

RECONSTRUCTION AND RE-EDUCATION OF DISABLED SOLDIERS AND SAILORS.

Lt. Col. Casey A. Wood, M. C., U. S. Army

OFFICE OF SURGEON-GENERAL, WASHINGTON, D. C.

Number of different disabling injuries and what is being done for them in this and other countries. Read before the American Academy of Ophthalmology and Oto-Laryngology, August 5th, 1918.

We all know what happened to the soldier and sailor disabled in our former wars. After a few brief weeks of hero worship, marked, perhaps, by a kindly tolerance of his oft-told tales of adventure in the army and on the battlefield, he was given a pension, and in some old soldiers' home or as a dependent upon the semi-charity of neighbors or relatives, eked out a half-forgotten existence, a bore to himself and useless to his country. It is true that a few of these returned invalids, in spite of their handicaps, resumed their former occupations or adopted some new industrial activity, but their number was so small as to be almost negligible.

As a matter of fact, the obstacles that lie in the way of a resumption of industry after the combatant has passed weary months in the field and in various hospitals, are to the sick or wounded man almost insurmountable. Unless prompt and continuous help is given, he lapses into a state of discouragement from which it is difficult to arouse him.

It has long been recognized that to be most effectual this mental and moral assistance, this "cheer up," this achievement of victory over wounds should begin at the earliest possible moment. It should be prearranged and definitely organized. All the belligerent countries have attacked the problem from this viewpoint and by conducting, chiefly through army nurses and medical officers, a campaign of education, early teaching the disabled man that his condition is not as hopeless as he probably thinks it is; and that the Surgeon General and other governmental agencies will see to it that his disablement will be reduced to the minimum, that he will be refitted for industry and that his family and he will be supported while he is undergoing reconstruction. He will be further assured that his war risk insurance compensation for disability will not be reduced as a result of his increased powers through reconstruction. Finally, a desirable job will be found that will enable him to become an independent, wage-earning

citizen, taking part in and enjoying the daily life of his own community.

This verbal campaign is further strengthened by posters displayed in the hospitals and on board ships returning from overseas, by cards entitled, "What every disabled soldier and sailor should know," by booklets telling how, when and where physical and vocational restoration is accomplished, and last, but not least, by moving pictures such as I expect to exhibit to you this evening.

In these and other ways we spread the good news that there are really no longer any "cripples," but only a readjustment of the soldier's reduced powers to altered conditions; and that the so-called disabled man can, if he wishes, improve and apply these powers, that he may even adopt a trade or profession more congenial or more lucrative—or both—than he followed before his injury or illness.

Who, let us now ask, are the war-disabled requiring rehabilitation?

Naturally one thinks of those who have lost eyesight or hearing or a limb, and these cases are of great importance and require special attention, but they really make up only about one-third of the whole number of the handicapped. We must not forget the tuberculous, constituting a large percentage of the total; the nervous patients, including the so-called "shell-shock" cases; the insane (curable and incurable); those with serious diseases of the heart; those that have been "gassed;" those with rheumatism, and many other internal affections. Any of these may suffer from a handicap even worse than the loss of a leg or an arm.

An approximate idea of the causes of disablement in the service may be obtained from a table based on statistics of the British army and navy during the present war. The figures indicate the number of cases in every thousand of disabled men, excluding officers:

Injury to eyes	32
Amputation of leg	30
Amputation of arm	19
Injury to leg not requiring amputation	121
Injury to arm not requiring amputation	82
Injury to hand not requiring amputation of whole hand	61
Injury to head (including six or seven cases of paralysis)	47
Hernia	7
Miscellaneous wounds and injuries (including about five cases of paralysis)	53
Total wounds and injuries	453
Disease of chest (including, say, 60 cases of tuberculosis)	124
Rheumatism	50
Diseases of heart	110
Epilepsy	11
Nervous cases	47
Insanity	9
Deafness (partial, or in comparatively rare cases, total)	26
Frostbite	10
Miscellaneous diseases (among which may be noted, besides a few cases of paralysis, Bright's disease, ulcer of stomach, debility, and varicose veins	160
Total causes of disease	547
Total wounds and injuries	453
	1,000

It may be added here that the number of men requiring extended treatment and vocational training constitute a relatively small proportion of the total number of those discharged from the army or navy. Although soldiers and sailors suffering from certain chronic diseases, such as tuberculosis, insanity and other mental and nervous disorders, may require treatment for a considerable period under special conditions, yet the time of retention in army hospitals after return to the United States will be relatively short. Some will be so nearly well as to permit of their discharge almost immediately upon landing. A considerably larger number will require treatment for a week or even a month or two in the general hospitals. About 90 per cent of the returned disabled men will be discharged after a comparatively brief period of treatment, and will require no special measures of physical or vocational reconstruction.

Our Government has already provided ample hospital accommodations for all these injuries and diseases, and hundreds of soldiers are now being restored to health through the agency of the Surgeon General and his medical officers, and receiving, meantime, physiotherapeutic, including occupational and other forms of prevocational training.

When the soldier or sailor has been as far as possible restored to health and is incapable of further military service, he is discharged from the army or navy and

transferred to the governmental civilian agencies, especially the Federal Bureau for Vocational Education appointed by Congress for the completion of his education or re-education.

It is estimated that the proportion of the total number of disablements calling for re-education for an occupation different from the one formerly followed by the disabled combatant is about 10 per cent. In other words, under the care of the Surgeon General will fall about 90 per cent of returned invalids requiring reconstruction, including those who will also under him complete their occupational career. When discharged from the army cured, as nearly as may be, of their injuries or disease, most of these are expected to pass directly into industry, following their old or a new occupation.

The task of finding a suitable job for returned invalided soldiers and sailors, and of exercising supervision over them after their return to work, will devolve on the Federal Board of Vocational Education, on the War Risk Bureau, and probably, also, on the American Red Cross.

As has been pointed out by Mr. Lakeman of the American Red Cross and others, "the reconstruction of the disabled soldier is, in the first place, a matter of public duty which is called for by every consideration of national gratitude and justice. This alone is a sufficient reason for the fullest expenditure of needed effort and funds. But also sound national economic policy requires that the state, in order to conserve industrial and labor resources, should make skilled workmen of its disabled soldiers and find them employment. After this war every soldier who returns to a condition of idle dependence on Government support will help to diminish the productive power of the nation. With the terrible wastage of men and materials, every ounce of constructive energy will be needed to repair the damage and to face the renewed intensity of competition in trade and industry. In this country, the channels of immigration are closed during the war, and the draft on the labor market is unprecedented. The supply of skilled labor is no longer inexhaustible. In the field of industry, as in that of natural resources, the era of waste and extravagance is over and every element of productive man power must be conserved as an indispensable national asset."

There is, however, another argument in favor of recalling the disabled man to a useful life. If the handicapped soldier or sailor, for any reason, fails to make use of his industrial calling—fails to take advantage of his opportunities—he becomes a part of the nation's human scrap heap, an unhappy victim of his own and perhaps of his family's indolence and neglect. It is the salvation of a soul as well as a body for which the rehabilitation activities are striving, and for the accomplishment of which we ask your assistance.

The disabled soldier's decision as to his future must be backed up by the unhesitating support of his community. No system of governmental or private vocational education can succeed unless the man's will to succeed is stimulated and his ambition aroused by a well developed public opinion. No Government bureau can exercise authority over the man's personal will to make or neglect his future. For example, it is easy to imagine what a powerful influence the supporting opinion of the family and of the neighbors may be in inducing a man to forego the false glitter of an immediate job in favor of the sound metal of thoro training for an independent future. To convert the man to the wiser view, it will sometimes be necessary to convert his family first. Certainly his friends, relatives and companions must believe in the desirability of this victory over wounds, and this will to conquer difficulties, if the disabled man is to be successful in the contest with the powers of darkness.

It is not possible in one evening to enter into details of the therapeutic care and training now being given to even the most important disabilities of our returned invalids, but I would like to say something more about the war deaf and the blind.

The blinded warrior makes a strong appeal to the emotions, although perhaps for this very reason the extent and importance of this form of disability has

been exaggerated in the public mind. The French experience indicates that less than one-half of 1 per cent of the soldiers wounded in battle are blinded, the reason being, probably, that injuries sufficient to make a man blind in both eyes generally prove fatal.

Some of the foremost educators of the blind have co-operated with our Government in devising, perhaps, the most complete system of re-education and after-care of blinded soldiers which has ever been undertaken in any country. Based upon careful study of the best methods of foreign countries, and supported with generous appropriations and ample private contributions, which make possible the most complete equipment, this plan will follow the soldier through all the phases of re-education, find him employment or a market for his products, and insure sympathetic and intelligent co-operation from his family and from the community.

To carry out this program, a fortunate combination of public and private resources has been effected. Through the generosity of Mrs. T. Harrison Garrett, a suitable estate of ninety-nine acres at Baltimore was offered to the Surgeon General and accepted as the central hospital and school for blinded officers and men. The Red Cross War Council has supplemented the army's plan by creating the Red Cross Institute for the Blind, in order that certain phases of the social and economic supervision of these men may be provided for. The medical officer of the Surgeon General's staff, Lieut. Col. James Bordley, Jr., who is responsible for the official army program for the blind, has also been made director of the Red Cross Institute for the Blind, and will work in close touch with the Federal Board for Vocational Education, thus insuring thorogoing unity of policy and control.

This combination of an official organization with additional private resources will make possible the continuous and perpetual care of blinded soldiers after they are discharged from the army. Not only education and placement are contemplated, but subsequent industrial supervision for the balance of the soldier's life. It must be remembered that many blinded soldiers will, in addition, be suffering from other forms of disability. In blindness caused in the industries, 98 per cent of the eye injuries are without such complications, whereas in war 40 per cent are multiple; that is, these blind men also have amputations of arms or legs, or both, facial burns, destruction of jaws, and so on. To these particularly unfortunate individuals the nation owes a lasting duty. Patriotic zeal will provide adequate care for these men at present, but only invested capital and far-reaching plans will make their future certain.

As soon as the American soldiers, blinded in battle recover from their immediate wounds at the base hospital, the special work for them will be commenced. At first, the chief effort will be to amuse them and inspire them with some degree of hope. Later, as the men improve, they will be concentrated at the port of embarkation in France, under care of a special staff which will expend the measures of elementary instruction, teaching the men to get about and care for their immediate needs; in other words, teaching them "how to be blind."

On the way home they will be grouped according to the degree of injury, and upon arrival in the United States they will be sent to the United States Military General Hospital No. 7 at Baltimore for further medical and surgical treatment and special teaching. The technical training given by the Government will be the very best obtainable and only paid professional instructors will be permitted to give it. The idea of the Government will be to place every blinded man in a condition to take care of himself and those dependent upon him.

Where it is possible for a soldier to return to his old occupation, or one allied to it, the aim will be to have him do so. Otherwise a special suitable occupation will be taught, and in many cases it is hoped that the man will be able to command a larger salary after taking the training than before he lost his sight. Among the trades and professions which will be taught are broom-making, mattress-making, rug and carpet weaving, telephone operation, farm work, mat making, tuning in piano factories, winding of coils for armatures, piano tuning

as an individual trade, salesmanship, massage, typewriting and dictaphone operating. There will also be ample facilities for recreation in the school, including table games, dancing, singing, cross-country walking, roller skating, attendance at theatres, musicals, and other entertainments, medicine ball, push ball, punching bag, relay races, gymnastics, field sports, running, climbing, swimming, diving, and skating.

Some of the most interesting features of the general plan will be made possible by the supplemental Red Cross appropriation. The Red Cross Institute, for example, will undertake to provide a home and transportation to Baltimore for the relative who will be responsible for the care of the blinded man when returned to his home. It is the intention to instruct one such relative in the Government training school side by side with the blinded soldier, as is now done in the British and French armies. The purpose is that the blind man's family may be informed as to his difficulties, ambitions, training, and needs, so as to prevent the mental deterioration which often results from false sympathy. Friendly relations between the family and teachers will be a potent means of stimulating the interest of the blind man.

A reel of the moving picture about to be shown you will further emphasize the vocational side of the care given our blinded men.

The Division of Physical Reconstruction of the Surgeon General's office has as its chief Colonel Frank Billings, and one of the sections of this division has charge of the defects of hearing and speech under the directorship of Lieutenant Colonel Charles W. Richardson.

After many months of planning, on July 23, 1918, at General Hospital No. 11, Cape May, New Jersey, a school was established for the defects of hearing and speech in connection with this hospital. The plan of the school is that all defects of hearing and speech among invalided returning soldiers from the A. E. F., as well as those who have become affected in the cantonments, will be instructed or re-educated in this school before they are discharged from the army. In other words, all soldiers or sailors evidencing deafness or handicapped along the line of this work will, while having their physical disabilities corrected and cured, be re-educated and their handicap raised.

Returned soldiers and sailors having defects of hearing from whatever cause, either from disease or as the result of casualties, are those whose hearing is so reduced that they are handicapped socially and incapacitated industrially. They comprise all the completely deaf and those whose hearing is so reduced that it requires an effort for them to hear, and who experience difficulty in communicating through the spoken voice.

Corrective speech work will be carried out on all neuropathic affections of the voice, all types of paralysis (medical or surgical), and those in that large class of cases due to facial maxillary injuries.

The fundamental principle which has been adopted in connection with this service is to hold the men in the control of the United States Army as pupil patients until their physical handicap has been relieved. It has been found, in studying methods adopted by the various co-belligerents, that the retention of the soldier until his handicap is removed, especially for defects of hearing, is the only safe procedure. In the French and Italian armies, where this method is pursued, all men get their re-education before they are dismissed; therefore, all men with this disqualification or handicap are obliged to accept the type of treatment which is instituted.

In the British army where men presenting these conditions are discharged, it has been found that re-education is not taken up by 74 per cent. Indeed, all efforts have been made by the Aural Commission in Great Britain through propaganda, through entertainments, through the offer of meals, etc., to entice these men back to accept re-education. To the many who wish to work they have even offered evening classes, and yet they do not avail themselves of it, except to the extent of 24 per cent.

We feel, therefore, that centralizing these cases and holding them in the service is by far the safest, sanest, and most certain means to accomplish this purpose of re-education.

It is also well to remember, and we wish it placed strongly before the public, that these men whom we propose to re-educate are not abnormal, but simply have become handicapped through the loss of a special sense in their service to the common cause of liberty. It should also be understood by the laity that, through the methods which we propose to adopt in re-educating these men they will not be handicapped; that they will simply be required to read speech with their eyes instead of hearing speech with their ears. They will be able to take part in all social pleasures, and they will be able to follow almost all the gainful occupations.

In the section of defects of hearing we will use two principal methods in teaching these people. One is the auricular oral method, which, through using the voice and various types of electrical apparatus, bring into activity a sense which has been impaired, either through violence, "compression," or neuropsychic conditions.

The second method, and the one that we depend on to the greatest extent, is lip or speech reading.

In those very rare cases in which the individual is too obtuse, or is unable to concentrate, we shall be obliged to make use of the manual method.

Defects of speech arise from various complex causes, and comprise those cases which will have to be treated by neuropathic methods, those cases which will have to be met by respiratory methods, and those which will have to be taught the principles of phonetics. A large number of cases of face injuries involving the throat will not only have to be treated phonetically, but also surgically.

This work of physical and vocational reconstruction was started at Cape May under the immediate medical control of Major John M. Ingersoll, with Captains Berry and Lampe as assistants. These medical officers, under the Division of Surgery of the Head, will take care of all medical and surgical aspects of pupil-patients.

The educational department has as superintendent Mr. A. C. Manning of Mt. Airy, Miss Enfield Joiner of North Carolina as principal, and four teachers —Miss Mary Louise Wimsatt, Miss Margaret Bodycomb, Miss Clara Louise Rockwell, and Miss Mary Thornton.

The first class began on Wednesday, July 24th, 1918, with seventeen pupils, many of them completely deaf, most of them extremely hard of hearing. They form a bright, intelligent, enthusiastic group of pupils, ardent in their desire to learn, appreciative of the service being rendered them, and enthusiastic in regard to their prospects for complete rehabilitation.

NOTES, CASES AND INSTRUMENTS

AN EFFICIENT LAMP FOR EYE OPERATIONS.

F. H. Verhoeff, M. D.

BOSTON.

Several years ago I was appointed chairman of a committee to provide satisfactory artificial illumination for eye operations at the Massachusetts Charitable Eye and Ear Infirmary. A previous committee had been unable to obtain on the market an entirely satisfactory lamp for the purpose, so I decided that it would be necessary to attempt to construct one. The lamp here described is the result of this attempt and has proved satisfactory in every way. It may be used to give either diffuse or focal illumination, but experience has shown that the former is seldom needed. The lamp consists essentially of a 6-8 volt nitrogen-tungsten automobile electric bulb, enclosed in a case, the light from which is focused by two convex lenses.

Fig. 1.

Fig. 1. Complete instrument showing convex lenses in place. (Verhoeff.)

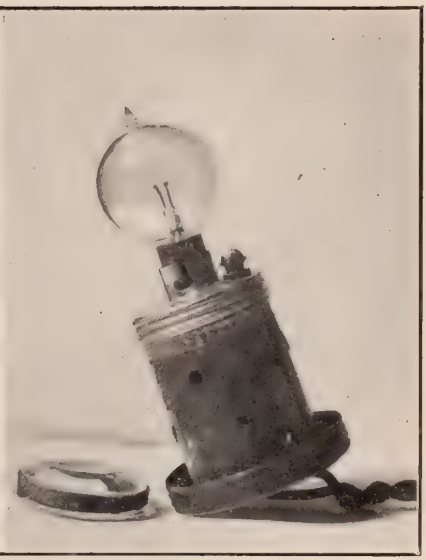

Fig. 2.

Fig. 2. Lamp fixed on smaller cylinder ready for insertion in the larger. (Verhoeff.)

The case is an ordinary pasteboard mailing case, 5.8 cm. in diameter and 13.6 cm. in length. At a distance of about 3.8 cm. from the bottom, a hole is cut of proper size and shape to take a smaller mailing case, 4.2 cm. in diameter. A section 2.5 cm. long is cut from the open end of the smaller case, the threads for the screw top being left on. This section is glued into the hole in the larger case. The large case is now wrapped with adhesive plaster which is also carried around the smaller case so as to hold it more securely. See Fig. 1.

To the tin screw top of the large case is attached a third mailing case 4.2 cm. in diameter and cut off so as to be about 8 cm. long, as shown in the illustration. Fig. 2. This is done by first attaching a solid cylinder of wood about 2 cm. long (cut from a curtain rod) to the screw top by means of screws, and then sliding the cut end of the smaller case over it. A large hole to take the electric cord should be bored through the wooden cylinder and screw top. A hole is cut in the screw top of the smaller case, and an automobile lamp socket soldered into it. Seven or eight air holes are bored through the walls of the inner case, and four air holes through the screw top (not

the closed end) of the large case. No other air holes are necessary. The cases should now be given at least two coats of shellac inside and out. This is important, as otherwise moisture will be precipitated upon the lenses when the lamp is in use. To improve its appearance, the large case may be painted black or covered with leather.

The lenses consist of two trial case lenses with edges unground, each 41.5 mm. in diameter, one of 9 and the other of 18 diopters. These are kept from contact by means of a cardboard cylinder ½ cm. long. They are conveniently attached to the lamp by means of a threaded lens holder removed from a bull's eye flash lamp of suitable size. (See Fig. 1.) If this is not obtainable, a holder can be made of cardboard and attached by means of adhesive plaster. The stronger lens should be outside and at a distance of 5.5 cm. from the lamp filament. For diffuse illumination it is simply necessary to remove one of the lenses.

To obtain the proper current of 6-8 volts, we have made use of an electric generator connected with the house current, but a rheostat may be used instead. Sufficient current may also be obtained from a series of five dry cells of 1½ volts each. It is important that the electric cord attached to the lamp should be in good condition as otherwise sufficient current may not reach the lamp. The lamp never becomes too hot to be held in the hand. One of these lamps has been in use almost daily at this institution for over two years and is still in perfect condition.

QUININ AMBLYOPIA FROM RECTAL ADMINISTRATION.

C. S. G. Nagel, M. D.

SAN FRANCISCO, CAL.

Lieut. Col. R. H. Elliot's concise review of Quinin Poisoning (this Journal for August and September last) would seem to invite practical addenda. In the history I wish to submit "the drug was pressed, at a time when it should have been totally withheld," tho not for the reason assigned by Elliot (page 549).

On July 18, last, Mrs. G. H. aet. 60, presented herself with the following history. After an operation of colectomy for "fibroid of transverse colon" (apparently no anatomic examination) on June 17, 1917, another operation for gall-stones was performed a few months later on October 26. After the failure to inject something into the brachial vein during second day after operation, an (hypodermic?) injection was made over breast. The following day the patient received an enema of unknown character for heart failure, after which she fell unconscious for about thirty hours; and thereafter found herself totally blind for a month. She then began gradually to improve for several months, but had apparently made no further progress during the last few months. Both the patient and her husband stated that according to current rumor a mistake in regard to the enema had been made. (The reference to the few days between second operation and onset of blindness has always appealed to me as probably garbled, for natural reasons; and perhaps, also, others—this being a medico-legal case.)

Present Condition—R. Hm. +0.75=0.8. L. Hm. +0.25=0.6 with +3, Snellen 1 with some difficulty. Visual fields contracted concentrically close to point of fixation, except that in the left upper quadrant of each field there is a normal roundish area for white, and all colors to a maximum extent of 25° right. The fundus in both shows retinal arteries as well as veins very narrow, with absolutely white sheathing, more particularly of the arteries (thickening of walls). Both discs are of extreme pallor and sharply defined. Macula normal. The diagnosis of quinin amblyopia was made, with just a possible alternative of embolism of both central arteries (of which—simultaneously bilateral—there are four cases now on record), or rather remotely, ischemia retinae from loss of blood. After five weeks of strychnin treatment, vision had improved to 0.9 and kept the same under same treat-

ment up to the beginning of November. Visual fields had remained about stationary.

During my attendance the people had begun suit against the sanatorium where the operations had been done, and by the end of October a settlement was effected. The operating surgeon could now be prevailed upon to make the following statement. For the prevention of "post operative gas pains" he had ordered 5 grains of quinin hydrochlorid per enema, every four hours. After 30 grains (some always being lost, he figures on an actual intake of 25 grains) patient showed signs of failing heart. This was not attributed especially to the drug. However, the order was changed to every twelve hours. Instead the nurse administered the clysma every two hours. After 60 grains in all, the general condition of the patient becoming alarming (weak pulse, etc.) the drug was stopped. Loss of consciousness and blindness following, as related by the patient. No eye examination was made at any time during seven months; only a short while before I first saw her another oculist had examined her. Regarding the indication for quinin in this case, the doctor said that he had been very enthusiastic about it after an interview with another practitioner who claimed to have had extensive experience with the method. A leading surgeon confirms my suspicion that the method is unknown to surgeons in general.

I have failed so far to get the consent of the patient to try sclero-corneal trephining as proposed by Elliot. The procedure as defended by him appears worth trying. We know that in fresh cases of ischemia retinae a reduction of intraocular pressure thru iridectomy has yielded excellent results. This fact led me to advocate at the A. M. A. meeting of 1905 the early performance of iridectomy in methyl alcohol poisoning where I believe an ischemia retinae precedes the cumulative effect of formic acid on the eye. I now wish to go on record as recommending prompt broad iridectomy for fresh cases of quinin amblyopia, since contraction of retinal vessels here is so uniformly a primary feature, together with low general blood pressure and mostly normal intraocular tension.

OCULAR LESIONS OF INFLUENZA.

EDWARD STIEREN, M. D., F. A. C. S.

PITTSBURGH, PA.

From a paper read before the Allegheny County Medical Society.

The following observations were made during the present epidemic of influenza on patients admitted to the South Side Hospital from the beginning of the epidemic until December 10th, 1918, and from a smaller number seen in private practice.

Influenza, 221 cases; died 27. Mortality 12.2%.

Influenza with pneumonia, 104 cases; died 70. Mortality, 66.3%.

Influenza with pregnancy, 6 cases; died 6. Mortality 100%.

Of the total number of cases the eye department was called in to see 54, or about 16%. These were for the greater part acute congestion of the ocular conjunctiva, not a catarrhal type, but marked by a dilation of the bulbar conjunctival vessels with some edema of the conjunctiva, and not infrequently with small subconjunctival hemorrhages which soon became confluent. Photophobia was present in practically all these cases.

Cold moist compresses gave the greatest relief and usually resulted in an amelioration of the congestion in from 36 to 48 hours. In the few cases with a catarrhal discharge the palpebral conjunctiva was inflamed and rough, a simple collyrium of zinc sulphat and boric acid affording prompt relief.

A young man, convalescent for about a week, developed a violently inflamed eye, the palpebral conjunctiva, especially of the upper lid, taking on a finely granular or mulberry appearance. The cornea developed a uniform haze of the epithelium, so dense that the color of the iris could not be determined, vision being reduced to inabil-

ity to count the fingers at 6 inches. There was no pannus.

The application of various astringent remedies, 1% silver nitrat, alum stick, copper stick, even rubbing with 1-1500 bichlorid were without avail; dionin had no effect on the corneal haze and atropin was impotent in dilating the pupil.

Finally, calomel dusted into the eye proved to be the remedy needed, and the patient is now steadily making progress, the lids are almost normal and the corneal haze is limited to an area covering the center of the pupil, while atropin, instilled three times daily, has dilated the pupil to about one-half of maximum.

Repeated smears were made from the discharge from this eye, but at no time could any organism be detected.

Two cases of double cellulitis of the orbit occurred. Both recovered without the formation of abscess under constant moist Ochsner compresses.

Four of the six cases of pregnancy were examined with the ophthalmoscope shortly before death. The other two cases had died before it was realized how fatal influenza is to a pregnant woman.

All four had abnormally large pupils, which responded feebly to light stimulus. Two had a marked neuro-retinitis, (one of these with small flame-shaped hemorrhages), one had a fundus picture closely simulating an albuminuric retinitis; while the fourth had an extremely cyanotic retina, the latter case being complicated with pneumonia.

SOCIETY PROCEEDINGS

ROYAL SOCIETY OF MEDICINE, SECTION ON OPHTHALMOLOGY

November 6, 1918.

President, Mr. W. T. Holmes-Spicer.

The first meeting of the season was opened by the president's address.

Corneal Changes Following Inflammation.

The President first thanked the Section warmly for having elected him to its post of honor, and then proceeded to give an address, aided by numerous sketches shown by the epidiascope, on "Changes in the Cornea Which Follow Attacks of Various Forms of Inflammation." He said this subject had received but small attention in the literature.

After ophthalmia neonatorum, sometimes very little was to be seen but the existence of vascular channels, yet the stagnation of the lymph circulation might bring about slowly advancing changes after all the inflammatory appearances had long since subsided. The presence of clear lines in cases of old corneal ulcers had been described by but few observers, altho they had been long known, and had been seen before the introduction of the loupe. Nettleship described the linear paths of clear corneal tissue in large diffuse lipomata, the latter having probably arisen after small spots in infancy; while Fuchs discussed the various linear formations existing in the cornea, suggesting that the lines were due to changes in the lymph system and nebulous area. The best description extant of these lines was that by Sydney Stephenson. In one of his cases the lines traversed a nebula with opacity, and there had been repeated attacks of corneal inflammation early in life. Story stated he had seen lines of this character in interstitial keratitis, and he thought they were due to a clearing of vessels. The picture presented to the observer varied according to the depth of the vessels concerned. Besides the surface invasion of trunk vessels, the terminal capillary loops of the limbus were seen involved, these vessels not arising from any main trunk. This was common in marginal inflammations, such as trachoma and acute interstitial keratitis, in which vessels invaded the cornea at all depths.

It was quite uncommon for vessels to disappear and leave no trace; even though empty of blood, they could be seen as silky threads on the surface, or as clear lines beneath the surface. The vessels in one layer of the cornea did not interfuse with those in another layer. The first necessity in the production of these conditions was a destruction of tissue. The contraction which followed that either interfered with nutrition, or interrupted the flow of lymph, leading to stagnation and the deposit of salts. Arcus senilis was more likely to occur in eyes which have been the subjects of corneal ulceration.

The author then dealt in detail with the various forms met with.

On the motion of Mr. E. Treacher Collins, seconded by Mr. William Lang, the meeting accorded to the President a cordial vote of thanks for his address.

Dilatation of Retinal Veins and Arteries.

Dr. Harley Goldsmith described and showed a case of excessive dilatation of retinal veins and arteries in one eye. When examined a few weeks ago for admission into the army, the surgeon said the vision of the affected eye was better than that of its fellow. The upper temporal vein was enormously congested, and the corresponding artery much dilated. Mr. Pooley showed before the Section, in 1909, a case of similar appearance which he regarded as angioma.

Nocardiasis of the Lacrimal Gland (Actinomycosis).

A paper by Dr. J. B. Christopherson and Major R. G. Archibald, of Khartoum, was read by Mr. Hepburn on "A Case of Primary Nocardiasis of the Lacrimal Gland, Caused by a Species of Nocardia Hitherto Undescribed."

The authors said the lacrimal gland appeared to be one of the most remarkable glands in the body. Having few disorders of its own, it fulfilled its destiny undisturbed by the disorders of the outside world, content to be left alone to administer its secretion to the great master tissue, the eye. The disease recorded in the paper represented nocardiasis, or actinomycosis, in which the causal agent was a germ or fungus, which grew readily aërobically and produced arthrospores.

The patient, a male aged 22, was admitted to the hospital suffering from a swelling of the right eye and inability to open it. The duration of the case was three and one-half years. There was neither scar nor wound visible. The eyelids could not be everted, but when raised a thick yellow discharge poured out, and the whole conjunctival surface of the upper lid appeared to be rough and granular, with deeper ulceration in parts. The swelling was painless, and was of dough consistence, tho without edema. There was a bulging forwards of the fornix of the conjunctiva. No lymphatic glands were enlarged, and the sight was unaffected. The eyeball itself was not invaded, nor were its movements involved; neither were photophobia or lacrimation present.

Under chloroform, the growth was dissected away. It appeared to have commenced in the lacrimal gland, and to have spread into the upper lid, invading the tarsal cartilage. It extended also somewhat between the eyeball and the bony orbit, along the ducts of the lacrimal gland.

Sections showed the morbid histology commonly associated with a fungal infection. A portion of a grain flattened between a slide and cover-glass showed that it was composed of the typical nocardial bacilliform hyphae, with rounded bodies or spores, the whole being held together in a dense matrix.

The paper then proceeded to describe the reactions in various culture media, and gave an account of the mycology. At the date of sending the paper the animal experimentation had not been concluded, but the condition did not seem to be pathogenic to the grey monkey.

Lieutenant Colonel R. H. Elliot said that tho actinomycosis was extraordinarily common in the endemic center of Madura and in Madras, yet during the many years he had practiced in the latter city he had not seen a case of it in the eye or any part of the orbit.

Mr. Leslie Paton expressed the cordial appreciation felt by the Section of the care taken by the authors to ensure the

safe arrival of the paper and specimens, especially as neither of the gentlemen was a member of the Section.

OPHTHALMOLOGICAL SECTION OF THE BALTIMORE CITY MEDICAL SOCIETY

November 20, 1918.

Dr. Fleming presiding.

Recurring Growth at Limbus.

Dr. Pearce showed a case of a peculiar epithelial growth of the limbus of the right eye, with the history that the patient had been under treatment several years; and that the eye had been operated upon three times for pterygium, with the recurrence of growth after removal. The cornea is now nearly completely covered with a peculiar leathery epithelial proliferation, a small portion of the cornea down and in still being free.

Discussion: Dr. Crouch said that he recognized the patient as being one that he saw in 1911, at which time there was a small area covering the cornea at the temporal side and at that time he advised removal of a portion of the tissue for microscopic study, with the result that the patient disappeared from his observation.

Dr. Downey mentioned the fact that he had seen the patient for about two months recently, and that the epithelial extension had been very slow. It was the universal opinion that a portion should be removed for examination, and if malignant should have X-ray or radium treatment; and, if the process continued, enucleation of the eye.

Destruction of Lid.

Dr. Pearce also showed a case of rather extensive destruction of the lower lid in a woman of thirty, which, in the absence of Wassermann, was held to be a breaking down of a gumma.

Interstitial Keratitis.

Dr. Clapp showed a case of interstitial keratitis, which was brought before the Section to exemplify his opinion that some of the interstitial cases which do not improve under specific treatment are in all probability associated with a tubercular infection. This patient had been under treatment for many months with a very little improvement and specific treatment within the hospital was followed by very little change. The von Pirquet reaction was positive and the eyes have improved much more rapidly since the giving of tuberculin.

He also showed a case of Dr. Fleckenstein's which had been given tuberculin for two years, and the improvement had been very marked.

Carcinoma of Orbit.

He also showed microscopic sections of two carcinomas of the orbit, the first being a squamous cell epithelial growth starting in the bulbar conjunctiva, which did not improve under radium and later required exenteration of the orbit.

The other case was one of basal cell epithelioma which had been under radium treatment for five years, finally resulting in exenteration.

Sarcoma of Iris.

Dr. Friedenwald reported a case of sarcoma of the iris in a woman that he saw nine years ago for refration and later in 1915. In March, 1917, however, there was found a slightly pear-shaped pupil in the left eye, which upon examination with loupe showed a small growth at the nasal side of the pupil jutting out into the anterior chamber. Vision was 20/20; Wassermann reaction negative. The case was sent for consultation to Dr. de Schweintz, who confirmed his diagnosis of sarcoma. A very large iridectomy was done in May, 1917, and the tumor was sent to Dr. McCleary for examination, who reported spindle cell sarcoma. The vision has since remained fair with no recurrence to date.

C. A. Clapp, *Secretary.*

ABSTRACTS

Lister, W. T.—Pathologic Aspects of Certain War Injuries of the Eye.

The Lancet, July 20, 1918. The writer presents a selection of observations made on certain war injuries of the eye which appeared either novel, or elucidated other allied conditions, or exhibited a contrast between civil and military experience. These are presented under five heads: 1. Ruptures of the sclera; 2. Concussion changes; 3. Suppurative changes; 4. Changes in the vitreous, and 5. Effect produced on retina and choroid by penetrating foreign bodies.

Regarding ruptures of the sclera: In civil life the greater number take place either immediately above, or above and internal to the cornea, and about 3 mm. from the limbus. In military practice, tho some are similar, others are quite different, and the cornea is burst forwards, or equatorially, or split into numerous petals. Many theories have been advanced to explain the site of civil ruptures, but none has received universal acceptance. Variations in thickness and strength of the sclera, and the amount of support derived from surrounding structures are important factors in determining the site of the rupture, but not the only ones, since otherwise all ruptures would take place in one zone. Lister points out that unless the sclera is actually perforated by the missile itself, rupture does not start from the point of impact, but occurs at some considerable distance from it. This is because the resistance of the envelope to pressure is one-third greater than its tensile strength; hence the eyeball would tend to burst at some distance from the point of impact, sooner than give way at this point.

Experience shows that ruptures most commonly take place either in the equatorial zone, about the line of impact, or opposite the point of contact (contrecoup), and it would appear that these two sites are associated with two different kinds of blows. I. The ruptures caused by slowly moving objects which strike the eyeball directly, without penetrating globe or orbit, occur in the equator round the line of impact at a point where the globe is least supported. This group will include the bulk of ruptures met with in civil life; they are caused by direct impact of comparatively slowly moving objects, such as stones, fists, sticks, boots, or cows' horns.

The site of impact is at the anterior half of the eye, usually below or down and out, owing to the protection afforded to other parts of the eye by the brow and nose; the line of impact from a blow below the cornea will pass from below upwards and backwards; the least supported portion of the equator to that line of impact will be above the cornea, viz., the site at which civil ruptures usually occur. II. In contrast to these we find that ruptures caused by rapidly moving missiles (to which the bulk of those seen in military practice belong) which pass through the orbit but do not strike the eye directly, occur at the side opposite to the point of impact—i. e., at the point of contrecoup; for example, missiles passing through the back of the orbit cause the cornea to be burst forwards, or if they have passed through the side of the orbit the rupture may be found near the equator on the opposite side. The writer explains in detail why the different forms of blows bring about different forms of rupture.

Next, the ruptures of the eye caused by a missile passing through the globe, are considered: When the foreign body passes through the *back* of the eye, the cornea is shot forward and the contents ejected, more or less of the cornea being torn away. When a sufficiently large fragment enters the eye in *front* there is an explosive effect, and the sclera is split into numerous petal-like lobes by radial ruptures extending backwards from the point of entrance. The elasticity of the sclera will accommodate the entry of small particles without rupture. When, however, the

fragment is of such a size and has such velocity that the united effect of the increase in volume caused by the entry of the body, together with the distending force of the pressure wave set up by its impact, is sufficient to overcome the elasticity of the supporting coat, widespread ruptures occur, splitting the sclera into leaves radiating backward, often close up to the optic nerve. This section of the article concludes with a comparison between ruptures of the sclera and fractures of the skull, tho the dissimilarities of the two structures prevent such a comparison from being very close.

The subject of some of the less common concussion changes is taken up. In discussing those of the retina and choroid it is pointed out that commotio retinae is frequently observed in military practice and does not differ from the civil type; several cases were seen where early pigmentation of the macula followed commotio, either as fine peppering or as somewhat diffuse greyish-brown spottings; a picture noticed, but not seen described, consisted of a peculiar striated appearance, evanescent in character, extending for several disc diameters round the macula, coming on when the white haze had disappeared and suggesting that the retina was still swollen and wrinkled. The more grossly concussed fundus met with in military practice, when unobscured by vitreous hemorrhage, is described as one of the most dramatic ophthalmoscopic pictures: In the early stages there are extensive, rich-red clouds of hemorrhage (retinal, choroidal and subhyaloid) interspersed with gleaming white patches; the latter gradually fade, and in the course of time are replaced by plaques of fibrous scar tissue, frequently festooned and sometimes perforated by round or oval holes; these plaques are probably patches of coagulation necrosis due to rupture of choroidal and retinal vessels in the immediate neighborhood, thus cutting off the blood supply and nutrition of certain areas of the retina.

The writer goes on to a consideration of the sites at which concussion changes occur—1, adjacent to the site of impact; 2, at the macula; and 3, immediately opposite the site of the impact. Missiles passing thru the side of the orbit may cause concussion changes at any of these situations; but blows on the front of the eye give rise to changes, as a rule, only at the posterior pole or around the macula. When missiles pass thru the orbit, the area always concussed is that adjacent to the site of the impact; so constant is this that in certain cases of wound of one side of the head, with no apparent disturbance on the other side with the exception of some blurring of vision, the ophthalmoscope by revealing concussion changes in the eye of this side will enable us to state with certainty, not only that a foreign body has passed across the head and thru the orbit on the opposite side to the wound of entrance, but also to define its course—a piece of information which may be of great value to the general surgeon. The macular concussion changes from blows on the front of the eye are common and to be anticipated as a result of bruising at the site of contrecoup; but such changes due to blows on the side of the eye are difficult to account for excepting that the greater vascularity and delicacy of structure in this region renders it more vulnerable; there may be two distinct patches separated by a band of normal retina. In some cases of a lateral blow on the eye, hemorrhages were seen immediately opposite the site of impact corresponding to contrecoup effects in the brain and sclera.

The effect of concussion on vision is discussed and such experiences summarized. In general, these correspond to those generally known. It is pointed out that in severe cases sight may be completely lost for a few days and may then be regained—a fact which may be of the greatest importance in deciding the fate of a wounded and concussed eye. Comparing the concussion changes of the fundus met with in civil and military life, the following striking difference is pointed out: In civil life, where concussion is due to blows of

direct violence on the anterior half of the eye from comparatively slowly moving objects, detachment of the retina and holes at the macula are comparatively common, while severe concussion changes are rare; in military practice, where the concussion is produced for the most part by rapidly moving missiles passing thru the orbit, detachment of the retina and holes at the macula are infrequent, while severe concussion changes are nearly constantly present.

Regarding suppurative changes in the eye, the writer says that, as would be expected from the large number of penetrating wounds of the eye in warfare, suppuration is common; but panophthalmitis, whether exogenous or endogenous, is usually not of an acutely infectious type; there is seldom much pain, and tenonitis with consequent proptosis and chemosis is not often marked. In endogenous or metastatic forms, Lister found much difference in the clinical picture according to whether the anterior or posterior vessels of the eye received the septic embolus. When the anterior half of the eye is first infected, there is early exudate into the anterior chamber and anterior portion of the vitreous and marked discoloration of the iris. When the choroidal or retinal vessels are the seat of the primary infection, the first sign is a general diffuse edema of the bulbar conjunctiva, loss of fundus reflex and dimness of vision, without discoloration of the iris or exudate in the anterior part of the eye; in the course of 24 hours there is added slight proptosis and practically complete loss of sight.

Next are described the changes which are produced in the vitreous, retina and choroid by penetrating foreign bodies; and finally the correlation of lesions with defects in the field of vision are discussed. Regarding the last, the writer says that the delicate localized lesions of the retina are in reality wonderfully neat physiologic experiments, for which in peace time it would be difficult to obtain either the subjects or the license. Experimenters have, by dividing portions of the retina in animals, been able to trace out the course of degenerated fibers in the optic nerve, but naturally, they were unable to correlate these lesions with defects in the field of vision in the lower animals; but in these war experiments on man we can correlate the visible lesions with defects in the field, tho we are unable to complete the examination by tracing the course of the degenerated fibers. Thus we find that lesions above or below the horizontal plane cause a defect in the field out of all proportion to the local disturbance—i. e., there is a "distribution defect," in addition to the local defect due to the lesion. This is due to the lesion having not only damaged the spot which is struck, but also involved nerve fibers which were passing on to a more peripheral part of the retina. The "distribution defect" is fan shaped from the point corresponding to the lesion and extending toward the periphery; the nearer the lesion is to the disc the greater the blind sector, and vice versa, which agrees with the accepted distribution of the nerve fibers in the retina.

When the lesion occurs in the horizontal plane there is no "distribution defect," but the loss of the field is limited to the area corresponding with the lesion, as would be expected, for the fibers supplying the retina in the horizontal line arch around from the disc to their destination, and therefore these lesions would only involve the nerve fibers at their termination.

Sector defects following bruising of the retina are strikingly similar to the sector defects in the field following solitary patches of choroiditis.

C. H. M.

H. K. de Haas.—Dangers from Arsenic in Daily Surroundings.—Geneeskundige Bladen, v. 20, No. 2.

This writer has found arsenic 32 times in the urine of sufferers with optic nerve inflammation of more or less specific character. Examining among his last 8,000 patients those who had optic nerve disease of a similar character, he had none with lead-intoxication, 4 with albuminuria, 3

with glycosuria and 22 with arsenicuria.

Comparing this with the reports of the ophthalmologic institutions in The Hague and Amsterdam he found the same percentage for albuminuric retinitis, while during that time no case was reported with lead intoxication or diabetic retinitis. Optic nerve affection and arsenicuria must be generally found in the Netherlands, and will appear more frequent when the facts are known. Ten of his cases had previously been seen by other ophthalmologists and he has the case histories of 5 more given him by colleagues.

The history of the first patient needs a rather full report. Mrs. —— came on July 3, 1907, with R. 3/60 and L. 6/6, hyperopia 4, 5 D. The amblyopia was connected with a right strabismus convergens. On March 2, 1912, she returned with complaints of difficult vision. This had gradually developed during the last months. The fundus was ophthalmoscopically normal, only below the left disc a spot in the retina seemed somewhat edematous. A few days later she complained of seeing spots and colors, suffered with a pronounced photophobia, and could not read or sew. The vision had not changed materially. The suspected spot in the retina was larger; showing in the direct image very fine, light, glistering points; also beaded capillaries. Here, therefore, was a retinitis, difficult to distinguish, situated in the superficial layers. The papilla had a normal color and border, only the veins were a little thick.

During the following days the process progressed along the course of the nerve fibers, and reached in some 2 weeks the macular region. Metamorphopsia was complained of, which showed that the process had gone deeper, reaching the layer of the rods and cones. "Everything seems to dance," relative and absolute, mostly negative scotomas and photopsies vexed the patient. During the following 3 weeks the retina regained its normal aspect, beginning at the disc, following the course of the nerve fibers in the direction of the macula, but not so regularly as the disease had done. No abnormality, objective or subjective, remained behind.

A scotoma corresponded with the diseased part of the retina, larger in the direction of the macula than the retinal lesion indicated. During some attacks the patient indicated scotomas, for which diseased retinal spots could not always be found, only a slight retinal hyperemia being seen. The patient's sturdy child remained always well and nursed. The urine was free from albumin and sugar. A tenia was present. The Wassermann was negative. The child was weaned, and the tenia destroyed. Looking for a cause of the intoxication much naphthalin was found in the linen in the bedroom; but its removal had no influence. The preceding summer the family had moved, the house had been painted and papered and floors broken open. Instead of "mouse-wheat," "rats-bane" was dusted about. On detection this was removed as well as possible. Was here a case of arsenic poisoning?

There were no symptoms of the conjunctiva, of the skin, respiratory tract or intestines, only some attacks of retinitis. Even before receiving K. I. she had a slight gingivitis, sometimes superficial pains in her face, sometimes intense dizzy spells, and rarely brief obscurations, during which all light perception would be absent. The urine for a week after the patient had been in the hospital contained arsenic, but so little, only a few thousandth parts of a milligram per liter, that de Haas did not consider that this could have any pathologic importance, especially as the examining chemist stated that he and his assistant did not have arsenic-free urine.

After a few weeks in the hospital the patient returned home free from complaints; but had a recurrence at the end of April; went away visiting, returned home cured at the end of May, and had another recurrence in June. The relapses were, like the first attack, superficial retinitis leaving the deeper layers intact. The cause must be in the house. These appearing and disappearing attacks were later somewhat explained.

During the next few years two events made arsenic still to be considered as cause of the retinitis, notwithstanding the examination of the urine wrongly considered negative. During a quiet intermittent spell the patient went to her dentist, who filled a tooth temporarily with arsenious acid. The same evening the patient had intense photophobia and only next morning had edematous spots, and very fine white foci in the eye. The same evening the dental canal was emptied, and the attack disappeared in a few days. The other attacks had ended more gradually, especially those where the patient remained at home.

Investigation showed that not more than 3 mg. of arsenious acid could have been put in the tooth. Looking for the cause the attention was attracted by the metal teapot. The patient stopped drinking all tea and coffee; and, as she had been advised to drink much, she consumed 1.25 liter of Vichy water daily. A sharp recurrence followed, on account of the two milligrams of arsenic which Vichy water contains per liter. The urine contained quite an amount of As. The air drawn from the locality where the paperhanger had strewn the ratsbane before the moving was found negative as to arsenic. But this was while the weather was good, and there was no moisture, so it was probably quite dry between that floor and the second story. At the end attention was drawn to the green painted wainscot in the kitchen, which was downstairs; this paint contained much arsenic.

Arsenic was also demonstrated biologically with a Penicillium culture. These fungi showed the possibility of evaporation of arsenic during moist weather; and also of their own presence at such times.

If it is true that chronic arsenical poisoning can be the result of combinations in gaseous form, formed by fungi from solid arsenical combination, thus may be explained the capriciousness of their appearance, and especially the stoppage of the attacks without the patient leaving the house. During moist weather, becoming warmer, when condensation appeared on the rather cold walls, the fungus throve and complaints came. During the dry weather and while it became colder, even if it rained, the fungus pined away, and the patient recuperated.

After removal of the paint, only one slight attack happened in the very rainy and mild month of January, 1916. No fire had been lit in the parlor so that we can safely surmise that it was moist there, and also in the ceiling above. After the fire was lit the attack disappeared. Vision is now as it was 10 years ago.

All cases had the following picture in common:

It was an affection of the peripheric optical conducting apparatus, limiting itself (as far as this is possible to determine clinically) to the most central neurons of the retina. The neurons were affected in the retina, or in the optic nerve, or in both. The lamina cribrosa did not form a barrier. Often the retina suffered first. Sometimes the retina did not show any distinguishable deviation. Then the changes of the disc alone were insufficient for differentiation from the classical intoxication amblyopias.

As far as objectively visible the inflammation was focal. This agreed with the functional disturbance, never being total blindness, remaining as local defects in the visual field. If the attack lasted long, fine pigment changes appeared in the pigment layer showing that the deeper retinal layers were affected. The light sense was little disturbed. Only a few patients, and they lightly, showed photophobia, which was so intense in the first case. The very fine superficial changes in the retina were only visible in the erect image. The retinal hemorrhages, when present were small, less than the diameter of an ordinary bloodvessel.

In at least eight cases, after removal from the arsenic source, an existing, previously stationary papillitis increased. In a retinitis four weeks, and even later after the ingestion of arsenic had stopped, appeared still papillitis. Under the same circumstances retinal hemorrhages (mostly only few,

situated near the papilla) would show.

The arsenical neuro-retinitis has mostly a continuous protracted course, lasting longer if the patients had been exposed longer. Many cases lasted 6 months or longer, after the ingestion of arsenic had stopped before recovery, or a permanent condition of atrophy. The central vision became damaged not only with retinitis, because this resided in and around the macula (sometimes exactly and only here); but also because the maculopapillar tracts of the nerve were first and mostly affected, even with the absence of any retinal changes. If atrophy was present the temporal quadrant was affected by preference. In serious cases the disc in its entirety became atrophic. In cases which had been long influenced by the intoxication, the vessels kept their normal caliber, unlike quinin intoxication. The visual field did not become contracted, but the para- and central scotomas, the permanent central blindness, made many needy persons. If vision became 1/10 it was only eccentric. *With few exceptions, the patients were otherwise healthy persons.*

Most of the cases could point to the wallpaper as the source of the intoxication. One soldered much, mostly tin. One, as a cooper, handled for many hours daily galvanized iron hoops, in the tin of which was much arsenic. Many became affected in an institution where the lids on the pans in which the meals were prepared, were made of galvanized steel; that is sheetiron which was not tinned over but covered with zinc. This contains regularly arsenic. Here and there the zinc was absent. Could it have been dissolved in the food? Investigation showed that the institute inhabitants absorbed less than 200 mgrm. of As_2O_3 daily; that is such a quantity of arsenic that it becomes after oxidation 200 mgrm. As_2O_3. This quantity of arsenic at the utmost, combined in unknown form, in which it reaches daily the intestinal wall with the food, made two persons lose their central vision.

Of the 13 people examined in the institution, 2 had an arsenic-free urine, altho undoubtedly arsenic was absorbed. Not every one's kidneys have the same permeability for arsenic. The seriousness of the ocular manifestations did not depend on the quantity of arsenic found in the urine. Only a few of the many hundreds, living in the same conditions, showed ocular disease. None of the other institution physicians had found the slightest indication of arsenic poisoning during the last year. The only two who received permanent damage, were two sisters. Zinc kitchen utensils are dangerous, unless the zinc proves on examination to be free from arsenic.

One of the 35 patients, a boy of 18 years, when last seen had still 10 mgrm. of arsenic in his urine. He could count fingers at 4 meters with R. He could not see more until of 5/20 he saw well one letter, of 5/15 two letters and of 5/10 he read them all correctly (E T L F N). He had with the same eye less than 5/60 and more than 5/10 vision. Somebody who tumbles over a pail, which he does not see, while he is able to pick up a pin, becomes almost suspected of simulation. This is the result of central sharply limited defects in the visual field.

De Haas could find in the literature 8 cases of arsenic optic nerve poisoning; 6 thru administration of arsenic as medicin, or as a poisoning dose by the mouth, and two thru wall coverings. Arsenic poisoning of the optic nerve has been described rarely up to date, except thru atoxyl, arsacetin, etc.

The normal urine does not contain arsenic. The urine can contain arsenic in clinically healthy persons; when they live in surroundings containing large amounts of it.

Of the 35 cases there were 32 where De Haas made the clinical diagnosis of neuroretinitis arsenicalis, and arsenic was found in the urine in which the quantity did not amount to more than 60 mgrm. per liter urine. The three exceptions could be readily accounted for.

The consequences of the loss of vision thru avoidable arsenic in the practice of de Haas alone represent a value of a million guilders. E. E. B.

MacNaughton-Jones, M.—The Sterilization of Local Anesthetics.—The Lancet, June 29, 1918.)

The writer suggests a simple but effective method of preparing a sterile solution of cocain or other local anesthetic which may also contain adrenalin. It consists in preparing a solution of sodium chlorid together with the anesthetic or anesthetics and adrenalin, each constituent being present in such quantity that a dilution with many (e. g., 40) times the volume of water, will give a solution containing the requisite percentage of each. The preparation is placed in a sealed phial or ampoule and kept until required. Sterile water is added immediately before injection. Experiments demonstrated that even if the preparation be inoculated with the ordinary forms of bacterial contamination the presence of concentrated salt renders it sterile in a few days.

A simple method of preparing the concentrated solution is to take the quantities of anesthetic, salt, etc., required per 1,000 and dissolve in water; but make up to 25 instead of to 1,000. The concentrated solution suggested contains:

Kerocain or procain (novocain)	3.25	(13%)
NaCl	3.25	(13%)
Adrenalin chlorid solution (1 in 1,000)	8.00	(32%)
Water by weight (or metric)	ad 25.0	(100)

This solution, prepared without antiseptic precautions, and after contamination with bacillus coli and other organisms, was sterile a week after preparation. When diluted with 40 times its bulk of water it contains 3.25 parts per 1,000 of both procain and sodium chlorid, gives perfect anesthesia, and has an osmotic pressure approximately equal to that of a 4 per 1,000 (0.4 per cent), solution of the latter salt. The adrenalin is not in sufficient strength to arrest hemorrhage, but secures prolonged anesthesia. A certain amount of hemorrhage during the majority of operations is easily controlled; and, in his opinion, is preferable to the risk of a subsequent hematoma, which he has seen develop on more than one occasion.

If a 2 in 1,000 (0.2 per cent) solution of cocain be desired the formula would be modified as follows, and the concentrated solution would be:

Cocain hyd.	2.	(8%)
Sodium chlorid (approx.)	3.75	(15%)
Adrenalin chlorid (1 in 1,000)	6.	(24%)
Water by weight to	25.	(100)

It is suggested that a solution be prepared 40 times the strength of that required for injection, because increments in the dilute solution of ¼, ½, ¾ or 1 per 1,000 correspond to an increase of 1, 2, 3, or 4 per cent. in the concentrated solution, and these are the increments usually desired.

Magitot.—Traumatic Variations of Ocular Tension.—(Ann. d'Oculist. v. 155, p. 1). This author refers to a previous work in which he proved that ocular tension was dependent on the amount of blood in the uveal vessels. (See A. J. O., v. 1, p. 587.) The aqueous is a practically stagnant fluid permeating the fibrillar neurogleic sponge called the vitreous. Being incompressible, it gives way when the erectile choroid tissue becomes distended, and becomes richer in albuminous contents as the result of serum passing thru the vessel walls.

Therefore the permeability of the iris angle and the canal of Schlemm has no influence on ocular tension. If the aqueous were concerned in tension, an increase in the contents of the eyeball caused by a hemorrhage into the anterior chamber should be followed by a rise of tension instead of the fall which actually occurs. The regulation of the blood in the uvea is under the control of the intraparietal nerve cells of the eyeball, at least they are without doubt the point of origin of the reflex caused by the stimulus of the trauma, which results in an excitation or inhibition, with consequent hyperemia or anemia of the choroid.

Traumatic lesions of the eyes can be divided into two groups: (a) where the lesion of the orbit predominates,

and (b) where the ocular lesion is the more important. The first group consists chiefly of hemorrhage into the tissues, which interferes more or less with the venous flow. However, it does not completely check it, and moreover there is an immediate beginning of absorption which causes a progressive decrease in the interference. In three cases which he quotes there was a decided rise in tension following interference with the venous outflow, altho the eyeball was uninjured. In a case of unilateral anthracoid furuncle of the lid with orbital phlebitis the tension on the affected side was 45 mm. and on the healthy side 15. The vision was normal, however, there were no fundal changes, the pupils were equal, the tension fell in the same ratio as the inflammation subsided and the stasis was relieved.

In group (b), characterized by the predominance of ocular symptoms as opposed to orbital, there may be either a rise or a fall of tension. In some cases there is an inhibition of the intraparietal nerve cell, resulting in a passive dilatation of the arterioles, an overfilling of the veins of the uvea with a turgescence of the latter and a rise of tension. In other cases there is an excitation of these cells, a contraction of the arterioles, less blood in the veins, shrinking of the uvea and fall of tension. It is impossible to say why the trauma has one effect one time and another the other, for it is impossible to point out the exact spot where the trauma may be acting. Then, too, a moderate effect may stimulate and a more severe one may inhibit the physiologic action of the same cells. In a case of ophthalmomalacia very striking oscillations of tension were noticed.

In considering the disease glaucoma, the error is frequently made of confusing the symptom hypertension with the disease itself. As a matter of fact, there are many ocular affections, some inflammatory, some angiosclerotic, some purely traumatic, which, according to the point of attack of their etiologic agent on the vascular element of the uvea, or its innervation, may cause a high or low, transient or permanent tension.

His conclusions may be summed up as follows:

Traumatic variations of ocular tension have two causes—one passive and the other active.

1. Mechanical interference with the orbital venous circulation. These hypertensions last as long as the circulatory obstruction is present.

2. Troubles caused by the action of the trauma upon the intraocular vasomotor nervous system. C. L.

Sakai.—Sensitiveness of the Cornea and the Conjunctiva.—Nippon Gank. Zasshi. Dec., 1917.

The results of his experiments follow:

1. The conjunctiva has the sense of touch as shown by Nagel, but less, relatively than the edges of the lids, skin of the face, etc.

2. The bulbar conjunctiva on the part exposed by the aperture of the lids has a little less sensitiveness than the other parts.

3. The cornea has the sensation of touch.

4. The cornea and conjunctiva fail to have the sensation of warmth, and this is likewise so of the caruncle and semilunar fold.

5. The bearable heat is 42-43° (Cent.).

6. Pain is especially experienced in the cornea.

7. It is in spots in the conjunctiva especially in the lids, more than that of the bulb. This condition may be observed also in the cornea (some portions being more sensitive than others).

8. The difference between the sensitive points is the least on the free border of the lid (8.7 mm.), while that of the conjunctiva is 15 mm.

9. Sensation to chemical substances is less than that to cold.

KOMOTO and H. V. W.

Wallis, Hoare, W.—Operative Technic and After Treatment of Cataract Extraction.—(The Medical Journal of Australia, 1918, p. 297.)

The writer says he ignores the ques-

tion of ripeness, and operates on the riper eye if the patient cannot carry on. After making a conjunctival flap he does a large ring-shaped capsulotomy and a peripheral iridectomy. Twenty-five per cent argyrol solution is instilled for two days before and the conjunctival sac irrigated with normal saline, just before operation. He contents himself with this provided a culture shows no danger from the conjunctiva. He lays great stress on the importance of retraction of the lids, uper and lower, by an assistant using Lang's or Harman's retractors and pulling forward and away from the globe (Smith). The loss of vitreous he looks upon as comparable to shock, hemorrhage or sepsis in general surgery. Intraocular irrigation with saline after extraction and eserin are used. A sterile vaselin swab is applied and held in place by plaster and a wire mask. Aged patients are out of bed in two days. A large number, irrespective of the type of operation, have to undergo discission.

GERMAN OPHTHALMOLOGY.

A myth is sometimes worthy of careful consideration and scientific study. There has been an attitude of exaggerated appreciation on the part of Americans toward Germany, and its supposed achievements in ophthalmology, so out of proportion to the real share Germany has taken in the development of ophthalmology, that it is worth examination. The power to inspire confidence and unmerited respect is an attribute of the successful quack the world over. The disposition to use propaganda to advance the interests of "kultur" is a German characteristic. At this time of careful sifting it is well to inquire how far the respect shown for the ophthalmology promulgated in Germany is justified by real scientific leadership; and how far it is based on unthinking acceptance of an assumption of superiority that does not exist.

The expansion of knowledge, interest, and achievement which characterizes modern ophthalmology, began in the middle of the last century with the use of the ophthalmoscope, the exact measurement and correction of anomalies of refraction, and specialization in practice. The use of the ophthalmoscope was given to the ophthalmologist largely by German workers. When Helmholz had solved the problems of physics involved in seeing the background of the living eye, Graefe, Jaeger, and their colleagues took the instrument and began making studies of the eye-ground. Babbage had invented such an instrument ten years earlier, but the English surgeon to whom he showed it failed to perceive its importance; and it was put aside unused, until the credit of its introduction had been secured for Helmholtz and Germany.

But the important practical improvements that have been made in the ophthalmoscope have nearly all been suggested and applied outside of Germany. Reute of Holland gave the perforated mirror, which Wadsworth of Boston and Loring of New York perfected in the tilted form. The socalled Rekoss disc was of little importance until the New York optician, Hunter, working for Loring, Knapp, and John Green, had perfected their forms of refraction ophthalmoscope. Morton of London suggested the other widely used mech-

anism for a practical lens series. The electric ophthalmoscope was suggested and perfected in America by Dennett, Marple, and their successors. The latest advance, in the large fixed ophthalmoscope, has been made by Gullstrand of Sweden.

The most important offshoot from ophthalmoscopy, the shadow test, skiascopy, has been wholly developed and principally used outside of Germany. It began with incidental observations by Bowman, was developed into a method by Cuignet, Mengin, and Chibret; and has been perfected by French, English, and American workers. Transillumination, first described in Germany, remained as little noticed and as unused as the Babbage ophthalmoscope for 30 years, until taken up by Swanzy of Dublin, and Würdemann and others in America.

The ophthalmometer, a ponderous laboratory instrument of Germany, that has measured the eyes of probably less than 100 persons in any generation, was first introduced as an instrument for clinical work, when Javal and Schiötz had based it on new principles and remodeled it. Since then it has been used on hundreds of thousands of eyes, in the practical measurement of refraction.

The scientific understanding, exact diagnosis, and practical correction of errors of refraction began and developed outside of Germany. From the time of Young, Airy, and Stokes of England; of Donders, whose work in Holland, translated from the Dutch in Dublin, first received adequate publication in the new Sydenham Series in London; thru Landolt, Weir Mitchell, Thomson, Green, Dyer, Norris, Hay, Risley, Brudenell Carter, Hartridge, and Gould, the correction of ametropia developed to more than half of the work of the ophthalmologist, without ever being well taught or its importance fully understood in myopic Germany.

Operative ophthalmology comes down to us from an older time, and each generation modifies and readapts the older procedures. Cataract extraction had, of course, been introduced by Daviel before any German school of ophthalmology existed. The generation that followed him devised and used knives of all possible shapes, that of Beer remaining most generally popular. Graefe, choosing a narrower knife, such as had been used by Sharp, described what he called a modified linear extraction; which no one now practices, and which he soon modified himself. This, with a few such suggestions as Waldau's spoon, modified by Graefe, but properly supplanted by the Levis wire loop, constitute the chief original contributions of Germany to cataract extraction.

After Chevalier Taylor had claimed to do an operation for squint, and Bell had suggested a rational basis for it; Stromeyer worked out an operative procedure, and Dieffenbach of Berlin did this operation and exploited it to the world. Dieffenbach probably did it after Guerin of Paris; but he got into the newspapers with it first; and then every general surgeon from Moscow to Peru began to use and modify it. Dieffenbach's record of 3,000 cases in three years has probably never been broken. But so recklessly was the operation resorted to, and so bad were the ultimate results, that it quickly fell into complete disrepute. So when Graefe began to publish accounts of practically the same operation 15 years later, it was mentioned as Graefe's operation. Revivals of the squint operation brought about by Critchett and Snellen were better procedures; and much more in the line of modern progress than the Graefe operation. The muscle operations for advancement, tucking, and resection have all been developed outside of Germany. From German operators we have had only inferior elaborations or imitations, not even a new method of placing or tying the sutures.

The great advances of modern general surgery began with Lister's application of the discoveries of Pasteur. Sir Berkeley Moynihan has brilliantly shown how little Germany has contributed to this movement. In plastic surgery about the eyes, Germany has contributed less than England, France, Italy or even India; and now Amer-

ica's practical inventive ingenuity, turned to the solving of its problems, is achieving unprecedentedly good results in blepharoplasty and restoration of the socket. In the surgery of adjoining parts, of the brain, the sinuses, the hypophysis, America has taken the lead. West, of Baltimore, taught his window resection of the lacrimal passages in Berlin, apparently understanding that German surgeons and their students and imitators would never recognize its merits if taught anywhere else.

In view of the limited proportion of the advances in ophthalmology that can be traced to German sources, what are the factors that have entered into the making of the myth of German ophthalmology? A study of them can be of special practical value to American ophthalmologists today. The myth has been founded chiefly upon the statements and claims of Americans who went to Germany to study ophthalmology; and came home to impress the medical profession and the public with the mastery of it they had attained there.

When modern ophthalmology began to develop as a medical specialty, every medical school in America was a private business enterprise, dominated by general practitioners and surgeons who were strongly opposed to specialization in medicine. There was no reputable, well-educated physician in America formally attempting to teach ophthalmology. All that it was generally considered necessary to know about the eye and its diseases, was taught by the professor of general surgery in two lectures.

Under these conditions young men like Williams, Dyer, Green, Holmes, Noyes, and Agnew, who became interested in the subject, went to Europe to study it, under Bowman, Desmarres, Donders, Graefe, and Jaeger. Graefe himself had studied in Paris and London, then world centers for ophthalmology. Naturally the younger men who caught their interest in ophthalmology from its first teachers in America, as Wadsworth, the Derbys, Loring, Norris, Thompson, and others, turned to the springs of knowledge that had been so much to their teachers. A still younger generation found in Germany the laboratory opportunities that were still scarce everywhere, and a few utilized them.

The idea of finishing an education for ophthalmic practice by a year, more or less, in Europe became firmly implanted in the mind of the American medical profession. Germany offered certain conditions that were especially attractive to the student who had been biased with the notion that all he needed was clinical contact with cases of eye disease to make him an ophthalmologist. People raised for "cannon-fodder" can easily be utilized as "clinical material." From masses, compelled to live under conditions of poverty and social degradation could be built up public clinics of such size and subserviency as were impossible anywhere else in the world.

To the claims of these big ophthalmic clinics the American medical student was peculiarly susceptible. To see six cases of retinitis pigmentosa in one day, seemed a vast clinical opportunity. In his ignorance of real clinical study he did not realize that he could have learned a great deal more from one case studied for six days. In the last quarter of the nineteenth century, Vienna and Berlin had come to be regarded in America as clinical Meccas; and the priests of this religion lived by the fees of American students.

To have gone abroad to "study" served the purpose of impressing prospective patients; and few were capable of judging the character of that study or the value of its results. German ophthalmology including a superficial clinical acquaintance with the common diseases of the eye, a contempt for the careful measurement of ametropia, and an exaggerated desire to discover rare cases, became the popular standard of attainment for the eye specialist in America. More practical French and British clinical work, and the American passion for results, were needed to save ophthalmology from becoming a mixture of clinical superficiality and laboratory pottering.

When it became understood in German clinics that ophthalmology was unknown as a medical specialty in America, a very natural emigration of German ophthalmologists occurred. Julius Homberger was one of the first. But later came men like Knapp, Hotz and Alt, of scientific attainments worthy of the respect they received from their American confreres; and it happened that the first three ophthalmic journals published in this country were started by men who had been born and educated in Germany. Moreover, the first American institution for graduate teaching in ophthalmology was Knapp's Ophthalmic and Aural Institute in New York.

The student commonly has an exaggerated estimate of the knowledge and wisdom of his instructor. He ranks high the man who taught him, and regards him as an authority. Whether this feeling was exploited in the clinics, or in the literature of Germany, it produced a respect for German achievements in the field of ophthalmology out of all proportion to their scientific importance, a readiness to accept anything that came thru German channels, while important communications from other sources were unnoticed.

It seems to be natural for the German scientist to spend his time in the recording of minute routine observations, and in collecting bibliographies. There grew in Germany a mass of literature, some of which was valuable, and some merely cumbersome. Mackenzie had done much for ophthalmology in this direction; but in "Nagel's Jahrsbericht" and in elaborate bibliographies the Germans brought together all the papers related to each single topic. Their ophthalmic literature was often ponderous, sterile, and marked by sordid, bitter controversies on questions of priority. But its mass made an impression on those who did not read it; and students were able to search out in it, that which had not been gathered or preserved anywhere else. It helped to give plausibility to the myth of German ophthalmology; and substance to the commercial returns that myth was capable of yielding.

With ophthalmology universally recognized as an important branch of medical knowledge, and practice; with schools and literature developing in all parts of the world, the unreasonable reverence for German ophthalmology was doomed. But it is useful to know that its influence rested on two things: the establishment of institutions where ophthalmology was taught, and the development of a literature in which published facts were carefully preserved and collated. The comparative value of such institutions and this kind of literature need to be better recognized in America. When they are so recognized, we will develop better teaching and a more valuable literature than those which helped furnish prestige to Germany. E. J.

SILVER PREPARATIONS IN LACRIMAL SAC DISEASE.

Even yet, despite certain unpleasant medico-legal experiences of some American oculists, do we find many men using the silver solutions as the nitrat, argyrol, and protargol for injection into the lacrimal sac for dacryocystitis.

Now, the best of us abrade the lacrimal passage mucous membrane, and even occasionally make a false passage in sounding. Then too, in quite a proportion of such cases erosions have already occurred in the course of the disease; and the forcible injection of any fluid by the syringe may carry the solution into the tissues of the lid or orbit.

If this fluid be aseptic and colorless no great discomfort may ensue; but if such a substance as silver is used, which makes an indelible stain after exposure to light, permanent discoloration of the lower lid—a chronic black eye—may occur.

This, in the case of a young person, especially in a good looking woman, is a great disfigurement, which can not be removed by any known treatment. Certainly the courts have upheld the charge of malpractice in such cases

Reiterated warnings are necessary regarding these solutions, for their use is common in this connection.

H. V. W.

POST-WAR AVIATION

Whatever else may happen as a result of the war, one thing is certain, namely, that the knowledge acquired concerning the mechanics of aircrafts, and the training of thousands of aviators will bring it to pass that air transportation will soon aid, possibly rival, land and sea transportation. This will happen either as government controlled enterprises, or as large corporations similar to the present railroad and steamship companies or as individual action similar to the present use of automobiles. It requires no great exercise of the imagination to see the air filled with crafts devoted to sport or profit. Also, it is evident that if this occurs, in the course of time regulations concerning their conduct will become necessary. Will the world wait until the problem becomes complex, or will some far seeing statesman initiate these regulations now, before vested rights and customs have arisen to demand consideration? Will they be municipal, state, national or international?

It is not the province of this journal to discuss the question as to what level shall be occupied by each form of aircraft, and what the "rules of the road" shall be, nor any of the other regulations of similar character, but it is our privilege to call attention to one phase of the question, and that is the *medical* qualifications of the aviator. Two extremes are possible; one is to follow the custom that obtains in the case of automobiles, and permit any one or any age, physical condition and habits to become an aviator. The other is to follow the rigid requirements of the army aviation service. Of the two, the latter is by far to be preferred, but is there not the possibility of adopting less stringent regulations without sacrificing safety. For example, is 20/20 vision without glasses essential for peace time aviation? How far should correct color vision enter into the requirements? Is correct response to the equilibrium tests equally necessary for those who fly at low altitudes as those who fly at high? Should alcoholics and people of unstable mental states be allowed to fly at all? These and many other problems should be settled now, when flying is in its infancy. It will be easier to exclude unfit flyers before they start flying than afterwards. On the other hand, the enforcement of unjust regulations might keep many men from flying who really ought to be allowed that privilege.

It seems to the writer that the best way of settling the medical problems connected with the future of aviation is for the large, representative medical organizations—the American Medical Association, etc.—and the special ones in whose province these questions lie—the Ophthalmologic and the Otologic Societies—should appoint committees to study them, either separately or conjointly, and make recommendations to Congress, so that the regulations when made shall apply equally to all men and all parts of the country. Let us hope that the first of these to meet in 1919 will initiate the movement, and that the others will join in, so that we may have scientific and not haphazard regulation of what promises to be one of the greatest fields of human activity.

C. L.

BOOK NOTICES.

PHYSIOLOGIC OPTICS, by **Charles Sheard,** A. B., A. M., Ph. D., Professor and Director of Applied Optics in the Ohio State University. Reprinted from the American Encyclopedia of Ophthalmology. 8vo. 517 pages. 250 illustrations. Cloth. Price $5.00. Chicago, Cleveland Press, 1918.

Deficiencies in their training in physiologic optics are felt by many American ophthalmologists. Improved methods and opportunities for study of this branch are among the most urgent needs of our courses of preparation for ophthalmic practice. The most com-

plete book on the subject hitherto available in English, has been the book by Tscherning as translated by Weiland 19 years ago. Of Helmholtz work there was no English translation. As a student, the writer regretted this, for the German text was difficult and forbidding. He has sometimes wondered whether the absence of a good textbook has had something to do with the neglect of the subject by many ophthalmologists in America.

However that may be, from the time of Thomas Young, many of the most important original contributions on the subject have appeared in English. Now, in the work of Sheard, we have a treatise that beside doing justice to the facts and formulas gathered and developed by Helmholtz, brings together the large number of practical observations and propositions recorded by more recent writers, especially in English.

It is fortunate that, as it originally appeared in the American Encyclopedia of Ophthalmology, it is already at the command of the large number of subscribers for that work. It is also well to have it available to those who have not the Encyclopedia, by publication of this separate volume.

In any treatise on physiologic optics, the algebraic formulas that are so noticeable are likely to deter some ophthalmologists from reading it; and prove a real obstacle to those who do undertake its perusal. It is but fair to call attention to the fact that in this work many of the laws that are commonly expressed by such formulas, are also stated in clear, direct English. or are made clear by simple, well chosen diagrams.

It should be realized also that physiologic optics is a much broader subject than mathematic optics; and that many things here set forth need no mathematics to explain them. This becomes evident when we examine the table of contents.

Part I. Ocular Optics, including refraction at curved surfaces and catoptics, gives full scope to the methods of mathematics; but the other parts have much less use for them.

Part II. Monocular Vision, and the methods of objectively and subjectively investigating it, is less formidable and of greater practical interest. The same is true of the subsequent parts.

Part III. Qualitative and Quantitative Determinations of the Retinal Functions.

Part IV. Binocular Vision and Ocular Movements; and Part V, Binocular Vision and Disorders of the Motility. In these latter parts there is much of interest to every one engaged in ophthalmic practice; and little that will make an excessive demand on his preliminary training in mathematics.

It is not possible in this notice to indicate the many subjects discussed in this book, that must interest any one who wishes to understand the eye and its functions. It must suffice to state that it covers physiologic optics as that branch of science has developed up to date. Of the four brief appendices, not included in the original article as published in the Encyclopedia, one is devoted to "The Theory of Color Vision," as reviewed by Mrs. Ladd-Franklin; another to "Refractive Differences in Foveal and Parafoveal Vision;" and a third on "Stereoscopic Colors or Retiring and Advancing Colors;" all based on articles published within the year.

While ample justice has been done to the workers of other countries, those of America have not been slighted, while Maddox is referred to 14 times. Howe is mentioned 12, Stevens 14, and Savage 19; and Cobb, Ferree, Ives, Lippincott, Luckiesh, Nutting, Prentice, Weymouth, and others have their work adequately noticed. Among the American writings regarding physiologic optics may be found ideas that will not be permanently held; but even these compare favorably with the errors of the past, and all that are included in this work are worthy of study and consideration.

On the whole, this book is excellently written in clear, direct language. It contains a better and more complete account of its subject than any other treatise yet published in any language.

It is well illustrated, neatly printed, and has good indices both of subjects and names, beside the full table of contents. The appendices and indices, the principal additions made to the work as it appeared in the Encyclopedia, add much to the value and convenience of the book as a work of reference. E. J.

TRANSACTIONS OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, Third Series, Volume 39. 582 pages. Illustrated. Printed for the College.

This volume covers the transactions of the College for the year 1917. The 18 months that have elapsed since the publication of its immediate predecessor, illustrates the difficulty of getting high grade printing done under the conditions existing during the last year. Its principal interest to the ophthalmologist lies in the 59 pages devoted to the proceedings of the section on ophthalmology. These proceedings have already been published more than a year ago in the Journals which were combined to form the AMERICAN JOURNAL OF OPHTHALMOLOGY. The volume is a very creditable one and contains a number of important papers and discussions of general interest to all members of the medical profession.

Among these are communications on "The Significance of Spinal Fluid Findings," by Fordyce; and upon "Syphilis of the Central Nervous System," by Swift and Stewart.

TRANSACTIONS OF THE THIRD COLORADO OPHTHALMOLOGICAL CONGRESS, held in Denver, 1917. 59 pages. Illustrated.

The papers included in these transactions have already been published in the AMERICAN JOURNAL OF OPHTHALMOLOGY, and are reprinted from this Journal chiefly for circulation among the members of the Congress. E. J.

NEWS ITEMS

Personals and items of interest should be sent to Dr. Melville Black, 424 Metropolitan Building, Denver, Colorado. They should be sent in by the 25th of the month. The following gentlemen have consented to supply the news from their respective sections: Dr. Edmond E. Blaauw, Buffalo; Dr. H. Alexander Brown, San Francisco; Dr. V. A. Chapman, Milwaukee; Dr. Robert Fagin, Memphis; Dr. M. Feingold, New Orleans; Dr. Wm. F. Hardy, St. Louis; Dr. Geo. F. Keiper, LaFayette, Indiana; Dr. Geo. H. Kress, Los Angeles; Dr. W. H. Lowell, Boston; Dr. Pacheco Luna, Guatemala City, Central America; Dr. Wm. R. Murray, Minneapolis; Dr. G. Oram Ring, Philadelphia; Dr. Chas. P. Small, Chicago; Dr. John E. Virden, New York City. Volunteers are needed in other localities.

DEATHS.

Paul Chavernac, of Marseilles, was killed recently in active service.

A. H. P. Dawney of London, died November 8th, of pneumonia; aged forty-eight years.

Isaac H. Lent, Middleton, New York, aged seventy-two, a member of the Medical Society of the State of New York; consulting ophthalmologist to the Thrall Hospital, Middleton; died at his home, about October 20th.

Dr. Albert B. Mason, Atlanta, Ga., aged thirty-one, died at his home, December 4th, from pneumonia following influenza.

Dr. Wm. H. Moore, Martinsdale, Mont., aged forty, died at his home, December 1st, from pneumonia.

Dr. Thomas T. Perkins, Cliftondale, Mass., aged forty-five, died at his home December 6th, from heart disease.

Dr. Eugene V. Riker, Flint, Mich., aged fifty-seven, died at his home, November 25th, from pneumonia.

Dr. Glenn C. Spurgeon, Seattle, aged forty-four, a member of the staff of the Eye, Ear, Nose and Throat Infirmary, died at his home, October 29th, from pneumonia following influenza.

Capt. Halstead Robert Wright, M. C., U. S. A., Columbus, Ohio, aged forty-three, formerly instructor in physiology and pathology of the eye in the Ohio State University, died while on duty at the Base Hospital No. 14, Fort Oglethorpe, October 17th, from pneumonia following influenza.

PERSONAL.

Dr. G. A. Whitledge of Anderson, Indiana, has been elected a member of the American College of Surgeons.

Dr. E. DeWitt Connell, of Portland, Ore., is spending a portion of the winter in the East and South.

At the last meeting of the Ophthalmic Section of the New York Academy of Medicine, Dr. Arnold Knapp was chosen chairman

and Dr. Ellice M. Alger, secretary, for the year 1919.

Dr. Adolph O. Pfingst, of Louisville, Ky., has determined to discontinue treatment of ear, nose and throat diseases on January 1, 1919, and confine his practice to ophthalmology.

Dr. McCluney Radcliffe, of Philadelphia, recently read a paper on "Diseases of the Eyes in General Practice" before the Dauphin County Medical Society, Harrisburg, Pa.

MILITARY NOTES.

A son of Dr. Alexander Duane of New York City was recently killed in action in France.

Lt. Col. Casey A. Wood, for over a year on the staff of the Surgeon General, Washington, D. C., has received an honorable discharge from the Army. He will spend the winter in California engaged in literary work, especially in editing the final volumes of the *American Encyclopedia of Ophthalmology*.

Capt. W. E. Joiner, M. C., U. S. A., has been ordered to Base Hospital, Camp Fremont, Palo Alto, California.

Capt. Frank R. Spencer, M. C., U. S. A., is assigned to Hospital Unit 162, at present at Camp Lewis, Washington.

Dr. Thomas H. Curtin of New York sailed for army service abroad just before the signing of the armistice.

First Lt. John W. McCollon, M. C., U. S. A., assigned to Hospital Unit 162, at present at Camp Lewis, Washington.

Capt. Harry Vanderbilt Würdemann, M. C., U. S. A., appointed chief surgeon, eye department Base Hospital, Camp Lewis, Washington.

Lieut. Harry Boyd-Snee of South Bend has been promoted to the rank of Captain, and is located with the Base Hospital, Little Rock, Arkansas.

Dr. J. R. Sickler of Frankfort, Indiana, has been commissioned a captain in the Medical Corps and ordered to report at Camp Sevier, South Carolina.

Of the seven ophthalmologists of Jacksonville, Florida, three are still in the service. Major Norman N. Hegie was home for Christmas on a leave of absence.

Capt. W. R. Fringer of Rockford, Illinois, who has been stationed at Camp Joseph E. Johnston, Jacksonville, Florida, since August, received an honorable discharge December 10th and has resumed his home practice.

Lieut. Cowan of Philadelphia, formerly associated with the service of Dr. McCluney Radcliffe at Wills Eye Hospital, has been recently advanced to a captaincy, and is assisting Maj. Wiener at the School of Ophthalmology at Camp Oglethorpe.

Major Wm. T. Shoemaker, of Philadelphia, who went abroad as ophthalmic surgeon with the Pennsylvania Hospital unit, has recently been honored with the appointment of Consulting Ophthalmic Surgeon to all of the American Base Hospitals of England. It is expected that the promotion will advance Dr. Shoemaker to the grade of Lieut. Colonel.

The war fund for blinded soldiers and sailors founded by Mr. and Mrs. George A. Kassler of New York will supply the money needed to open an institute at Lille, for the blinded soldiers of northern France who wish to return near their homes in the territory recently evacuated by the enemy. This decision was taken on request of the French government.

Colonel Walter R. Parker has recently visited Philadelphia as the guest of the Ophthalmic Section of the College of Physicians, and gave its members a most interesting resumé of the work accomplished by the Division of Head Surgery of the U. S. Army. Col. Parker, as is well known, has been in charge of this division, and was permitted to visit Philadelphia by reason of a special dispensation of the Adjutant General of the Army. Following the presentation of Colonel Parker's paper, an informal supper was tendered him at the Union League by the acting president of the Section, Dr. S. Lewis Ziegler. Lieut. Col. George E. de Schweinitz was also present at the meeting of the Ophthalmic Section, and supplemented Col. Parker's paper by an interesting discussion of the important position the science of ophthalmology had been permitted to assume in the present war, as the outcome of the united efforts of a large staff of ophthalmologists now patriotically serving the country here and abroad.

MISCELLANEOUS.

Our San Francisco reporter says the flu is still raging but is beginning to ease up a little. He has seen some cases of acute glaucoma immediately following the influenza.

The Annales d'Oculistique announces that from January 1st, 1919, its subscription price will be raised from 25 to 30 francs per annum.

We are reminded by Dr. H. W. Hill of St. Paul that the masking of nose and mouth is not sufficient protection against the spraying of the influenza germ. He says germs that are coughed or fall into the eyes are carried directly into the nose by the lacrimal passages. Therefore it is highly necessary to protect the eyes against invasion.

Dr. W. S. Dodd, A. R. C., working at the Mejdel hospital unit, writes from Jerusalem at the American Red Cross: "The clinics numbered sixty to a hundred a day. Of course we had all classes of cases in medicine and general surgery, but by far the larger proportion of our patients were eye-cases.

"Of the 252 operations that I did in less than seven weeks, 222 were for the eyes. This is the number of persons operated on, most of them having more than one operation, perhaps on all four lids. so that I really operated on 408 eyes.

"There were some cataracts, not more than would be seen in the same number of cases elsewhere, but trachoma and its consequences account for almost all of the eye troubles in this land. I set out to treat these cases radically and secured fine results when I could keep the patients long enough for a reasonable after-treatment. But even so, the number of eyes that can be saved from partial and total blindness is large and the economic value of each eye thus saved is enough to make the prosecution of this line of work of the greatest importance for the redemption of the land."

OPHTHALMIC LITERATURE

These lists contain the titles of all papers bearing on Ophthalmology received within the preceeding month. These titles are all in English, some of them modified to indicate more clearly their subjects. These subjects are grouped under appropriate heads, the succession of groups being the same from month to month. In the group the papers are arranged alphabetically usually by the name of the author in heavy-face type. After the subject of the paper (Ill.) indicates the number of illustrations. (Pl.) the number of plates, and (Col. pl.) colored plates illustrating the article. (Abst.) shows that it is an abstract of the original article. (Bibl.) tells that the paper is accompanied by an important bibliography. (Dis.) means that a discussion of the subject is published with it. Under Repeated Titles are indicated additional publication of papers already noticed. To secure the earliest possible notice writers may send copies of their papers, or reprints, to 318 Majestic Bldg., Denver, Colorado.

SCAR-TISSUE CONJUNCTIVITIS IN ANIMALS—ITS RELATION TO INSECTS AND TRACHOMA.

F. B. Eaton, M. D.

SAN FRANCISCO.

This is an account of a disease, hitherto little studied, affecting the conjunctiva in horses, dogs, and other animals probably transmitted by insects and from its resemblance to trachoma offering suggestive analogies with regard to etiology of the latter disease.

Probably few ophthalmologists in this country know that animals, especially horses, cattle and dogs, are subject to a follicular conjunctivitis which, clinically, presents all the essential features of trachoma; i. e., scar-tissue, entropion, trichiasis, pannus, and corneal ulceration and opacity.

On July 1st, 1918, the writer was appointed Acting Assistant Surgeon U. S. Public Health Service and ordered to verify, if possible, trustworthy information to the effect that following the importation of horses, in 1875, from Illinois into the Sierra Valley, California, and from Kentucky into the neighboring Washoe Valley, a severe epidemic of "granular" conjunctivitis with entropion, etc., affected the horses and cattle in those valleys, and that coincidently a species of biting fly appeared, which bit the caruncle of horses, cattle and old dogs. The information included the statement that up to 1845 the native "broncho" was the only horse on the Pacific Coast, and that no equine eye disease was known in the horse country of the Sierra valleys until the horses were brought in from Illinois and Kentucky.

Pursuant to instructions I went to Loyalton in Sierra Valley, the elevation of which is 5,000 feet, and interviewed horse-dealers and a well-educated and experienced veterinary surgeon. The statement that horses were brought into the valley from Illinois about 1875 was amply verified; also the species of fly, the appearance of which is peculiar. So far it has not been identified by entomologists; also, its habit of biting men and animals at the inner canthus, but not on the caruncle.

Later I visited the headquarters of the California State Board of Health for information as to where in the State trachoma is prevalent; especially trachoma possibly finding its source within the State. It was found that the only large groups of cases known are those among Indians, Mexicans and Armenians; also, that occasionally a single case is reported from some remote part of the State.

Next, I inspected the remount depot at Camp Fremont near Palo Alto. The ranking veterinary officer in charge informed me that none of the horses came from farther East than Montana; and that in making the eye test for glanders, no conjunctivitis except a transient one had been found among the 3,000 horses. He also stated that he was born and raised in central Illinois, where an equine "granular" (follicular) conjunctivitis is common, especially in August.

When severe, this conjunctivitis is followed, in some cases, by entropion. The people of that region attribute this conjunctivitis to a fly, the life period of which is about six weeks, and which attacks more especially the inner corners (canthi) of the horses' eyes. The

farmers protect the horses' eyes from the flies by leather fringes, etc. In Illinois he had seen cases of scar-tissue of the conjunctiva in horses, always with "granulations," and had seen the same in dogs.

The search for trachoma in localities where there is also granular scar-tissue in animals, in California, was not further pursued, since it is evident that there is comparatively very little of either disease at the present time in the State; and hence there is no opportunity to test the possible connection between the human and animal disease by interinoculation, examination of insects, etc.

My conclusions were:

1. There existed, years ago, in Sierra Valley and Nevada, a local epidemic of equine and bovine follicular conjunctivitis, with resulting entropion, and corneal opacity.

2. No facts were found satisfactorily establishing connection between that epidemic and the importation of horses from Illinois and Kentucky (tho it is possible), or that the fly described caused the conjunctivitis, either by biting or the transference of the secretion.

3. There are flies, probably species of Tabanidae (horseflies), in California and Illinois, which bite by preference, the eyelids of horses and human beings at the inner canthus. That any fly bites the eyeballs of either men or animals, is unproven.

4. Equine follicular conjunctivitis with scar-tissue and entropion exists in California, but is uncommon. It is more frequently seen in dogs.

5. Equine follicular conjunctivitis with scar-tissue is similar in appearance to that in trachoma, especially in central Illinois in Summer, and there are facts pointing to its origin there from biting flies which bite the eyelids of horses at the inner canthus.

6. Equine conjunctival scar-tissue is similar in appearance to that in trachoma, especially in the last stage, and it is the cause of animal entropion.

7. Single, isolated cases of trachoma, apparently sporadic, occur in California in individuals living in remote places, the origin of which it has not been possible to trace.

8. The prevalence of an equine follicular conjunctivitis with scar-tissue and entropion in Illinois, in view of the well-known prevalence of trachoma in that State, indicates a possible connection between the two diseases.

PREVIOUS INVESTIGATIONS AND LITERATURE.

The existence of a source or sources of the trachoma virus in nature, other than contagion from person to person, is, by analogy of other diseases, reasonable; and seems a necessary postulate as regards its ultimate origin. Moreover, the endeavor to discover such a source would naturally precede and lead up to attempts to discover its microscopic character and biology. Scarcely any research has been attempted in this direction, except by the writer as recorded in two papers published in 1910.[1]

The difficulties are great; and the greatest of these are, of course, the insidiousness of the disease, and its contagiousness from person to person. Not only is the victim, and those about him, often unaware that he is afflicted until long after the disease is acquired, but he may have removed far from the environment where it was acquired. Again, if he resides in a locality where the disease is endemic, it is invariably assumed that his is a case of contagion from another victim. Even when a community free from the disease lives in contiguity to one afflicted, the immunity of the former has been ascribed either to non-intercourse of the two, or to a supposed racial immunity. Thus, in 1895, Dr. Foucher[2] of Montreal reported to the French Ophthalmological Society that he and six oculists:

"Have not observed a single case of trachoma among the Indians of Canada, . . . and meanwhile the savages live under conditions favorable otherwise to receptivity; insufficient nourishment, lazy and slovenly, syphilis, tuberculosis and eruptive affections decimate them. It is not the possibility of contagion that is wanting: In Manitoba the Crees and Santeux live side by

side with the Russian Mennonites in the same scorn of hygiene. The Mennonites are ravaged with trachoma and a great many of them are blind from this affection, while the Crees and Santeux remain secure."

For years this immunity was regarded as racial, but the evidence is now overwhelming that there is no racial immunity.

In 1913 Dr. W. H. Harrison, of the U. S. Indian Service, in an article on "The Existence and Prevalence of Trachoma Among the Indians of the Northern United States and Canada," stated:[3]

"I have found but one small band of Indians, numbering 346, wholly free from this malady, and these are a fragment of the great Chippewa tribe scattered along the north shore of Lake Superior. I am unable to account for the absolute immunity enjoyed, . . . when the members of the same tribe, living further inland, are so badly afflicted. The proximity of these people to Lake Superior with its opportunities for cleanliness, will not explain this difference, as all the bands of this tribe live on large lakes, and can, and do, enjoy the same opportunities for keeping clean, as those living along the shore of Lake Superior."

Later, in reply to a query of the writer, Dr. Harrison replied: "I am sure that these Chippewas (on Lake Superior), do not have the number of horses and cattle usually possessed by most Indians, because of the fact that for the past twenty or thirty years they have been engaged largely in the cutting of timber in the surroundings, as laborers for various lumber companies, and in carrying on their previous occupation as fishermen along the lake shore region."

Sulzer,[4] in his report to the French Ophthalmological Society, stated "The more we study the absence of trachoma in Switzerland, the less we comprehend it. Trachoma is not endemic in Switzerland. The Swiss inhabiting countries where trachoma is endemic are subject to acquire the malady. Returning to their native land they recover rapidly. We know of no epidemic of trachoma provoked by repatriated trachomatous persons. . . The principal factor in the immunity of Switzerland seems to be the elevation of the country above the level of the sea."

In those regions of the United States where trachoma has been endemic for many years among the native whites, such as southern Illinois, and portions of Kentucky, and West Virginia, we find in southern Illinois and eastern Kentucky, geographic features which, being favorable to certain insect life, seem to have a bearing on the prevalence of the disease in those regions.

A most valuable paper: "On the Prevalence of Trachoma in the State of Illinois," published by Dr. W. H. Wilder[5] in 1901, is suggestive, and was quoted by the writer in 1910. According to Wilder: "In the Illinois Eye and Ear Infirmary, as will be shown, most of the cases come from the rural population, and are of American birth. . . . For years it has been observed at the Infirmary that a great many of these cases come from the southern part of the State, and I have made tables showing the total number of cases from each county for a period of ten years, from 1891 to 1900 inclusive, and from these *have estimated the percentage of trachoma to population* on the basis of the census of 1900. The results are shown on the map, on which the lines (or bars) drawn to scale, represent the relative percentage in the different counties. . . . *It is clearly shown that the disease is much more prevalent in the lower part of the State between the Kaskaskia and Wabash rivers, and is not prevalent around the centers of population.*" (Italics mine.—E.)

In 1910, upon a map of the U. S. Geological Survey of Illinois, the writer added the lines or bars of Wilder's map representing the relative county percentages of trachoma.[6] Referring to this map, it is obvious that trachoma prevails *par excellence* in Clark, Jasper, Cumberland, Crawford, Lawrence, Wabash and White counties, all bordering the west bank of the Wabash river from north to south, and that in all this region there is a multitude of streams. Furthermore, on

reference to the legend of the map, it is seen that in these counties above all others, are many low, sandy, river and creek bottoms; while the central and northern parts of the State, on the contrary, are overlaid with drift, and the elevation is comparatively high.

In the highlands of Eastern Kentucky, where trachoma is believed to be more destructive and malignant than elsewhere in the world, the connection between the disease and the topography is as suggestive as in Southern Illinois; for the mountain inhabitants of Kentucky practically *live only along the beds of the many creeks* which, for instance, feed the middle and north forks of the Kentucky River. The map of the "Buckhorn Quadrangle" (U. S. Geological Survey), comprising parts of Breathitt and Perry counties, Kentucky, shows that in an area of about 186 square miles, except at a few central points, *there is not a single road that is not itself a creek-bed, and that all the homes are on these creek-beds.*

It is approximately the same in Lawrence and Johnson counties, but the feature becomes less in proportion as one goes northwest from the mountains. "These people," according to a brochure of the National Committee for the Prevention of Blindness ("Trachoma a Menace to America,," 1915), "live by themselves in little homes, rarely grouped so as to form even a small settlement, and almost completely cut off from the world at large. In the mountains, the creek-beds, which have known no shaping by the hands of men, are almost the only roads."

Now, these topographical features of "Little Egypt" and Eastern Kentucky furnish the typical breeding grounds of various species of the Tabinidae or horse-flies, which, entomologists tell us, breed in the water and wet soil, along and in precisely such sandy creeks and river bottoms. According to entomologists also, the adult Taband is a great water drinker, and can not live far from water, as it requires it for breeding and drinking.

VETERINARY LITERATURE.

In veterinary literature, follicular conjunctivitis in animals (horses, cattle and dogs), is a well-recognized disease, as well as its sequelae, scar-tissue, entropion, trichiasis, and corneal opacity and ulceration. By far the most complete descriptions are given by James Law,[7] who states that according to Fröhner 40 per cent of the race of dogs are attacked; and as occurring in horses, cattle and dogs: "It may extend over the sclerotic and palpebrae. Microscopically these swellings are found to be enlarged lymph follicles, with an excess of lymphoid cells. The disease tends to assume a chronic course and may cause entropion and other troublesome lesions. . . . In case they (follicles) prove obstinate, the conjunctiva may be cocainized and the follicles crushed with ciliary forceps. . . . In extreme cases Fröhner counsels the excision of the membrana nictitans."

Of entropion: "In the older animals it is largely determined . . . by old-standing disease of the conjunctiva and tarsus, with cicatricial contraction or adhesion. Trichiasis is usually, tho not always, present. In any case, the tarsus is turned inward so as to press upon the front of the bulb, or even to disappear entirely." The treatment, as in human entropion, includes strips of plaster, Gaillard's sutures, and plastic operations. Clinically, the above are pictures of what in human beings is called trachoma and its consequences. Veterinarians do not suspect trachoma, and give the disease other names.

In its last stages in horses, as described by veterinarians to the writer personally, the scar-tissue occupies the characteristic position seen in the human eyelids; i. e., near the edge of the lid and parallel thereto, the line of scar, as it were, forming the hinge of the entropion.

The pathologic identity of this animal scar-tissue conjunctivitis with trachoma can, of course, only be established by comparison of the diseased conjunctiva of men and animals in microscopic sections and stainings; more

especially with plasma stains, by which the infection of follicles by trachoma virus is made certain. (Mayou.)[8]

RESUMÉ OF THE SUBJECT.

While it is certain that there exists a scar-tissue conjunctivitis in animals, which, clinically is analogous to trachoma, there are, as yet, no facts establishing a contagion thru the conjunctival discharge from animal to man, or *vice versa.* If it is transmitted, experience with other diseases argues the probability that the transference is thru the medium of a biting fly. The fact that the attempted inoculation of animals (including anthrapoid apes), with trachoma virus has been uniformly negative, does not invalidate the possibility of such inoculation, or *vice versa,* thru a *biting* fly, since the fly in biting, pierces to the capillaries, and hence this form of inoculation is an infection of the tissues, and not a contagion to a mucous surface.

If it could be accepted, the hypothesis that animals and certain species of horseflies (Tabanidae), *when both are present in a region where trachoma and animal scar-tissue conjunctivitis are endemic,* stand in etiologic relation to the human diseases, would harmonize a considerable number of observed facts; facts which, in the writer's opinion, render it at present, the most promising theory on which to base a systematic search for the *source* in nature, of the disease. The hypothesis, however, at this time rests upon fragments of evidence, which, significant in themselves, are not yet coördinated.

There are yet undetermined facts needed to fully correlate those which are already known. Some are conflicting. For instance, in Switzerland, where trachoma is not endemic and exists only as an imported, contagious disease, there is an abundant fauna of horseflies. On the other hand, according to Abadie, the Bedouin Arabs are free of trachoma in spite of their constant association with horses. Nevertheless, these facts, according to Dr. E. C. Van Dyke, professor of entomology, University of California, an authority on horseflies and a medical man of experience, do not militate against the agency of biting horseflies and horses, *when both are present,* in producing trachoma. For, as he points out, horseflies cannot exist in the waterless Arabian deserts, while in Switzerland there are comparatively few horses; (144,128 in 1911).

There are many species of horseflies; they are widely distributed, and species occur in all parts of the world, and especially in Southern Illinois and the mountains of Kentucky. Naturally, the species which bite by preference the eyelids of men and animals, are to be suspected; those mentioned in this paper as having this habit, are yet to be identified as to species. To do this requires the cordial coöperation of entomologists.

In stables and barnyards the housefly (*Musca domestica*), outnumbers immensely the biting stable-fly (*Stomoxys*). The ordinary observer does not distinguish between them. Around stables, the houseflies, when they swarm, often dung upon the back of the hands; and this feces may be carelessly carried to the face and eyes. That this might be a source of trachoma seems plausible, especially in view of the now known agency of insect feces in causing typhus, trench fever, etc. But, trachoma is distinctly a rural disease; whereas houseflies also swarm in city stables where horseflies are rare, and in cities trachoma exists only as a contagion from person to person.

In justice to himself, the writer should state that this theory of the agency of animals and biting flies in causing trachoma, was not, primarily, a theory to which he endeavored to find and fit facts. On the contrary, during an extensive ophthalmic practice of nearly thirty years in the Pacific Northwest, he consistently and faithfully recorded the occupation and residence and history of all patients, which he drew from all parts of Oregon, Washington and Idaho. On tabulating the cases of trachoma, the vast majority were found to be farmers, stock men and stablemen; the last predominating. He was unaware that in Hungary stables are popularly held to be a source of trachoma. Later followed the evidence that horseflies attack the eyelids of human beings, especially the eyelids of the trachomatous.

Infections become attenuated in passing for a long period thru many bodies, and it is claimed that especially in Philadelphia, trachoma there "is a most attenuated form of the disease";[9] while on the other hand, in Kentucky, where the disease, if anywhere, originates in some extrahuman source, Dr. J. A. Stucky has testified to its destructive malignancy.

In conclusion, the writer's main purpose in publishing this paper, is to appeal earnestly to his colleagues, especially those resident in regions where trachoma is endemic and prevalent, for coöperation in securing needed facts proving or disproving the theory. It needs besides, a cordial and intelligent coöperation between veterinarians, entomologists, bacteriologists, parasitologists, and the medical profession. As to coöperation, ophthalmologists, collectively, are most ignorant of animal ophthalmology. There has been no cooperation between them and veterinarians.

In seeking to solve the problem of the etiology of trachoma, to restrict investigation to a laboratory search for the microorganism, which, in the weighty opinion of E. Treacher Collins,[10] "is of utramicroscopic dimensions," while neglecting an equally diligent search for the *source,* is not only illogical, but also contrary to the spirit and experience of preventive medicine.

I have found veterinarians, entomologists, parasitologists, etc., always interested in the investigation, and glad to render assistance by information and suggestion. In this respect the writer gratefully acknowledges the help given by Prof. R. W. Doane, entomologist, and Prof. W. H. Manwaring, bacteriologist, of Stanford University; and also by Profs. E. R. De Ong and E. C. Van Dyke, entomologists, and Profs. Traub and Hayes, veterinary surgeons, of the University of California.

CONCLUSIONS.

1. The most promising regions for investigation of the source of trachoma are eastern Kentucky and southern Illinois.

2. In these regions, the relative proportion of animal scar-tissue conjunctivitis to trachoma should be compared with the proportion in regions where trachoma is neither endemic or prevalent.

3. Cordial coöperation between entomologists, veterinarians and physicians is absolutely necessary, in order to determine the agency or non-agency of biting and non-biting flies, their species and habits, in producing animal scar-tissue conjunctivitis and trachoma, and as carriers of these diseases.

4. The pathologic identity or non-identity of the animal conjunctivitis with trachoma should be determined by microscopic sections and plasma staining of the diseased animal conjunctica, and inoculation of the human conjunctiva with discharge from the diseased conjunctiva of animals. These should, if possible, be made.

6. The normal eyes of individuals bitten by flies (especially Tabanidae), in trachomatous localities, should be guarded from contagion and kept under observation to determine whether or not they develop trachoma.

7. Due consideration should be given to the statements of the people living in trachomatous regions as to the origin of trachoma (animals, insects, etc.), and they should be guardedly questioned.

8. The most essential factors in solving the problem are: publicity, energetic field research, and cordial cooperation between medical and scientific experts.

9. Caution is requisite in questioning laymen; their opinions and observations should first be elicited, and leading questions avoided as much as possible.

THERMOTHERAPY OF CORNEAL ULCERS.

L. Weekers, M. D.

LIEGE, BELGIUM.

This paper, written by Professor Weekers while serving with the Belgian Army and unable to consult the literature of the subject, presents his method of producing sterilization of corneal ulcers and his experimental demonstrations of the possibility of effecting such sterilization without extending the destruction of corneal tissue.

During the war a large number of publications have been added to the literature of ophthalmology in America on the subject of thermotherapy of corneal ulcer. The most notable of these are by Prince,[1] Shahan,[2] John Greene, Jr.,[3] and Young.[4] I have, unfortunately, not had abstracts of any of these papers.

Before the war in different publications[5] I recorded clinical observations and experimental researches on the subject of thermotherapy of corneal ulcers and its prognosis. I simply propose here to review the work done before the war for the readers of the American Journal of Ophthalmology. In 1910 I published my first observations on the use of the galvanocautery for progressive corneal ulcer when local treatment proved insufficient. Since then thermotherapy has rapidly taken the place of cauterization, especially in Germany,[6] and tends more and more to replace it.

In my former publications I insisted on the principle of this new method of using heat in the treatment of serpent ulcer of the cornea in the following terms:

The cultures of the pneumococci are sterilized in 24 hours at a temperature of 42° C. (108 F.); in ten minutes at 56° C. (138 F.); and instantly at from 65 to 70° C. (149 to 158 F.). In the same way the cultures of the Morax-Axenfeld bacillus are killed in five minutes at a temperature of 56 C. (131 F.). Without reaching a temperature which kills the microbes immediately can we not with heat destroy their virulence and sterilize the ulcer without, by this method, destroying the corneal tissue? This is the principle of functional sterilization and Pasteurization, and it is used in bacteriology to prepare a culture media with a serum base. A medium rich in albumin cannot stand a temperature of boiling without being notably altered and losing its characteristics. In this method of "chauffage" we replace the rapid action of a high temperature by the prolonged or repeated action of a temperature less elevated.

Heat has been used in the sterilization of wounds[7] and in the treatment of simple chancre for a long time, Aubert being the first to note the excellent effect of prolonged heat on soft chancre; submitting the lesions to a prolonged elevation of temperature maintained during 12 to 18 hours reaching a maximum of 40° C. (104 F.), resulting in prompt cure. This elevation of temperature seemed manifestly to diminish the virulence and to cause the disappearance of the streptobacilli of Ducrey. Unfortunately this method, difficult of application, is not without danger. In spite of the application of cold compresses to the head the temperature of the patient reached

an elevation of 39.5° C. (103 F.). Therefore there was soon substituted for the above method the simple elevation of local temperature, the heating of the chancroid by local baths of steam and hot air.

One can resort to various processes in making applications of heat to a lesion as superficial and accessible as ulcer of the cornea. In my first attempt ten years ago I had recourse to the galvanocautery, and when the war began I was seeking to find the best application for the electrocautery and bring to perfection this method of "chauffage." The war has completely interrupted my experiments. My plan of procedure was as follows: By means of a rheostat the platinum filament of the cautery was carried to different degrees of incandescence from a dark red to a clear white. I have used an even, moderate heat of incandescence, which is easy to exactly determine, by holding the loop of the cautery during one minute close to the bulb of the thermometer without touching it. The thermometer under this condition registers more than 50° C. (122 F.). This temperature is less than the local temperature of the point heated, because of the extent of the cooling surface as compared with the extent of the surface heated. With a little practice one knows by the color of the platinum wire the degree of incandescence needed to obtain a sufficient heating.

The eye having been previously anesthetized the lids are held open, the cautery is moved slowly over the entire surface of the ulcer, as near it as possible, taking care not to touch the cornea, and paying particular attention to the progressive margin of the ulcer. In general the chauffage of the ulcer is continued for one minute. Under the influence of the heat the moist surface of the ulcer is subject to rapid evaporation, and drying is produced, so that it is convenient to interrupt the process and moisten the cornea with a physiologic salt solution before resuming the application of heat.

At one sitting such an application of heat is repeated two or three times, according to the gravity of the condition. In my earlier experiences I prolonged the application more than one minute. Further experience has shown that more prolonged and repeated applications are unnecessary. The single application is usually sufficient. It is very exceptional to have to repeat such intervention; and there is little reason to fear further progress of the ulcer.

The clinical results of such thermotherapy are quite favorable. In 1908 in the Eye Clinic at the University of Liége we secured the healing of all cases of progressive ulcer of the cornea by chauffage without cauterization. The efficacy of such heat is remarkable. When the microbes have attained virulence the chauffage cuts short the progress of the serpent ulcer, which cleans itself; and at the same time the hypopyon disappears. The influence of the treatment on the subjective symptoms is very evident. Immediately after chauffage the patient's pain is relieved and the amelioration continues. After cauterization, however, it is not rare to observe violent pain during several hours. For relief of this Vasek[8] administers a narcotic (sulfonal and morphin). After chauffage cure is more rapid than after cauterization. The reason for this is that by the former method the damage to the cornea is reduced to a minimum; whereas with cauterization the condition is aggravated. With the anesthesia and heat of the latter the cornea is rendered more opaque, and interferes more with vision. On the other hand chauffage saves the corneal tissue adjacent to the ulcer, making it possible to obtain a better result with the cicatricial cornea from a subsequent iridectomy.

We cannot attach great importance to statistics regarding the effects of thermotherapeutics in this condition, because the functional result in each case varies, not only with the treatment, but also with the site of the ulcer, the stage at which it was seen, etc. Different cases cannot be compared with regard to the efficacy of this treatment. But in spite of these reserves the statistics of the 47 cases of pneumococcus and diplobacillus ulcers that I have published before the

war are very favorable to the continuance of this method. The following are my results with regard to visual acuity:

	Cases
Loss of eye	0
Good projection	1
Hand movements	1
Counting fingers	15
5/60	13
5/36	10
5/18	4
5/12	2
5/9	1
	—
	47

Vasek published the following table of 66 cases of corneal ulcer treated with cauterization:

	Cases
Loss of eye	1
Projection uncertain	2
Good projection	6
Movements of hand	16
Movements of fingers	30
5/50	3
5/30	5
5/20	1
5/10	1
5/6	1
	—
	66

The chauffage of corneal ulcers is an intervention less violent than cauterization.[9] From this point of view the experiments I have made on animals

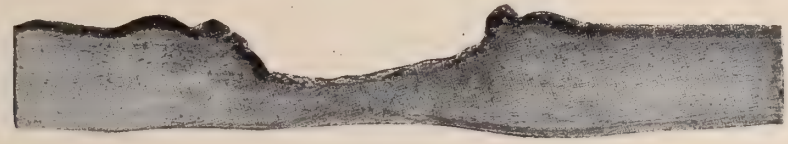

Fig. 1. Effect of cauterizing the cornea for superficial ulcer. Eye immediately enucleated. (Weekers.)

are very instructive. Fig. 1 shows the eye of a rabbit enucleated immediately after cauterization of a superficial ulcer. At the point of cauterization is observed complete destruction of the tissue of the cornea, which is considerably thinned at that portion. All parts of the cornea which have been touched by the cautery are destroyed. The cauterization also extends to a certain distance beyond the loss of substance. To this limit the superficial epithelium is altered and necrosed, and the corneal layers become edematous.

This destructive action of the cauterization explains that such intervention in corneal ulcer, which has already reduced the solidity and resistance of the cornea, may produce perforation, or favor it during cicatrization.

Fig. 2 shows a rabbit's cornea cauterized as in Fig. 1, and enucleated ten

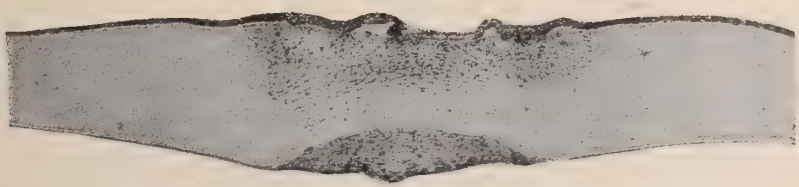

Fig. 2. Effect of cautery applied to superficial ulcer ten days after application.

days later. The cornea shows dense opacity at the point of cauterization. In experiments of this kind, as Ranvier has shown, the loss of substance is rapidly replaced, largely by the abundant proliferation of the anterior epi-

thelium of the cornea. Proliferation of the true corneal cells occurs also, causing the subepithelial infiltration reproduced in Fig. 2. Also there is seen immediately under the membrane of Descemet a mass of dense cicatricial tissue, due to proliferation of the endothelium of the posterior surface of the cornea, provoked by cauterization. This thickening of the deep cellular layer of the cornea is observed very constantly, tho not always so marked, and plays an important part in the opacification of the cornea following cauterization.

The thinning and proliferation of the cornea from cauterization as found at the end of three months, are illustrated in Fig. 3. The epithelium of the anterior surface is thickened, and also the endothelium of the posterior surface, but the thickness of these layers contributes little to the solidity of the cornea; while the thinning of the corneal parenchyma predisposes to subsequent perforation or staphyloma, and the thinned corneal parenchyma remains infiltrated and permanently opaque.

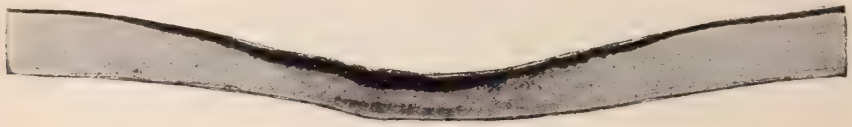

Fig. 3. Effect of cauterizing the cornea as seen at the end of three months.

The lesions produced in the cornea by chauffage, using a temperature sufficient to sterilize the ulcer and check its progress, are much more superficial than those provoked by cauterization. Fig. 4 shows the cornea of a rabbit subjected to chauffage by means of the galvanocautery for three periods of one minute each at short intervals; the eye having been enucleated immediately afterward. The lesions are simply an epithelial swelling, and a slight edema of the layers of the corneal parenchyma immediately beneath. In most of the preparations the corneal parenchyma at the point of heating is exposed by loss of the epithelium.

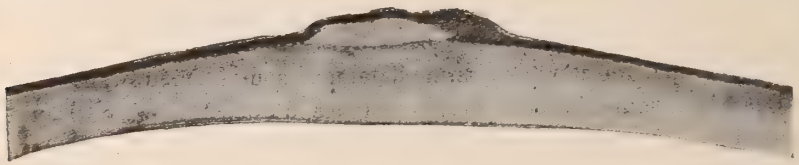

Fig. 4. Immediate effect of applying "chauffage" without cauterization.

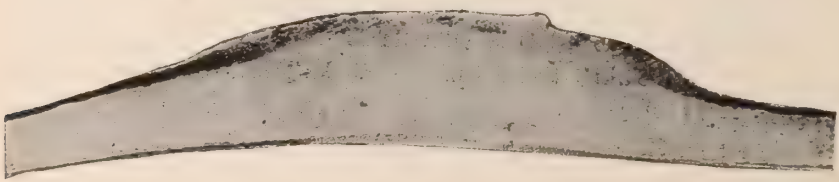

Fig. 5. Effect of "chauffage" three hours after its application.

The difference between these slight lesions and the destruction caused by cauterization (see Fig. 1), is remarkable. Here no true corneal tissue is destroyed, the parenchyma preserves

completely its thickness and strength. But for this a certain temperature must not be exceeded. When the heating is too intense or too often repeated, as I have noted in numerous experiments, it causes a very profound destruction of the cornea.

Figure 5 shows in a cornea three hours after chauffage the same conditions as in Fig. 4. The epithelium by proliferation tends to replace the portion lost. The corneal parenchyma is not the seat of any lesion except an edema, sufficiently marked to increase considerably the thickness of the cornea at this point.

When one heats the cornea of the rabbit, with the technic that I have described for the treatment of corneal ulcers, one observes at the point heated the production of a slight opacity, which thins out slowly and perhaps disappears completely. More often it persists under the form of a faint nebula, which is shown by section to be due to slight thickening of the anterior epithelium and a moderate infiltration of the subjacent layers.

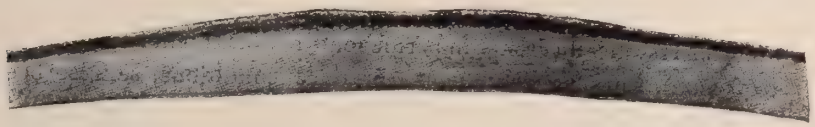

Fig. 6. Ultimate restoration of cornea almost complete after "chauffage." ((Weekers.)

BITEMPORAL HEMIANOPSIA DUE TO ACUTE SUPPURATION OF THE POSTERIOR NASAL SINUSES.

FRANK A. CONLON, M. D.

LAWRENCE, MASS.

This is the report of a case of this rare form of hemianopsia confirmed by a partial recovery after operation; and a review of current errors regarding the relation of the optic chiasm to the sinuses.

Bitemporal hemianopsia due to sinuitis is, considering the vast amount of literature published in recent years on ocular complications in nasal accessory sinus disease, an extremely rare occurrence.

There are but four such reports in all ophthalmic literature. Hirschman[1] mentions in a discussion that he has seen sinuitis cause bitemporal hemianopsia, while Wallis[2] and Evans[3] have both studied cases which were proven by operative results to be due to disease of the postnasal sinuses.

Levitzky[17] at a meeting in Odessa in 1908 demonstrated a case due to tuberculosis of the sphenoid.

Unilateral temporal hemianopsia due to the same cause has been observed by Gröholm,[4] Evans, Krauss,[5] and Fuchs.[6]

In a collection of 315 cases of bitemporal hemianopsia made by Bogatsch[16] in 1912, but one was considered due to postnasal sinus disease.

CASE.

2-16-17.—Mr. McG., 26 years old, married, three children, denies venereal infection. Has had what he called the grippe for two weeks; rather severe general headaches for three days; pain worse in morning and increased on moving head or turning eyes to left or to right. Patient says any exertion makes it worse. Some sensitiveness to light for the last 24 hours.

Ocular Examination.—Suggestion of swelling in both upper lids. Very slight injection of bulbar conjunctiva and considerable tenderness to pressure on left eyeball. V.—R. 20/30, L. 20/60. Muscular balance normal at a distance and near point. Right fundus normal, left disc slightly hyperemic. Veins somewhat enlarged. Questionable enlargement of blind spots. No central scotoma.

2-17-17.—Headaches still quite severe, especially on getting up in the morning. V. = R. 20/30, —.75 sph. = 20/20. L. 20/120 with—1.00 sph. 20/20. Right eye, fundus normal and fields normal. Left eye, disc blurred and swollen with retinal veins much increased in size. With a Peter's compimeter there is a slight enlargement of the blind spot to the temporal side and above. Peripheral field normal for white. Slight contraction of color field. No central scotoma. Pupil slightly dilated and reacts sluggishly to light.

Rhinologic Examination.—Septum markedly deviated to the left and touching middle turbinate. Posterior ends of both lower turbinates considerably enlarged, no pus or increased secretion noted on either side. Suction apparatus applied to both nostrils. No pus seen after treatment.

Patient examined by Dr. George Derby, Boston, on February 19th, who reported the following: V. = R. —1.0 sp. = 6/6. L. —1.0 sp. = 2/60. Right eye, field normal. Left, has an absolute central scotoma for white and colors, more marked and larger for green and red than for blue. Affects green over at least 10°. Red 10° below and 5° above fixation. Blue at least 5° below and 3° to 4° above.

One-fourth mm. object on Haitz chart.

Right nerve looks slightly fuzzy and vessels somewhat engorged. Looks like beginning slight swelling. Left 2 D. swelling with blurred outlines and large tortuous vessels. An unmistakable optic neuritis. No exophthalmos; but eyes, especially the left, very tender on movement, especially so on pressure. Dr. Derby advised X-ray and thought that nasal operation might be necessary.

Feb. 20th.—X-Ray plates made by Dr. Charles Burgess. No involvement of sinuses shown on plates. V. = R. 15/200.

V. L. Fingers at 6 feet. Right eye, disc swollen and very much blurred. Vessels injected and tortuous and impossible to take field. No color perception in either eye.

Feb. 22, 1917.—V R. = 6/200. L. = fingers at 3 feet. During the following week there was practically no difference in the appearance or vision in either eye, the patient being able to count fingers at only two feet. Operation had been advised but patient preferred treatment for the time being.

Suction, applied to each nostril, was used daily; and a slight amount of pus was seen in the left middle meatus and

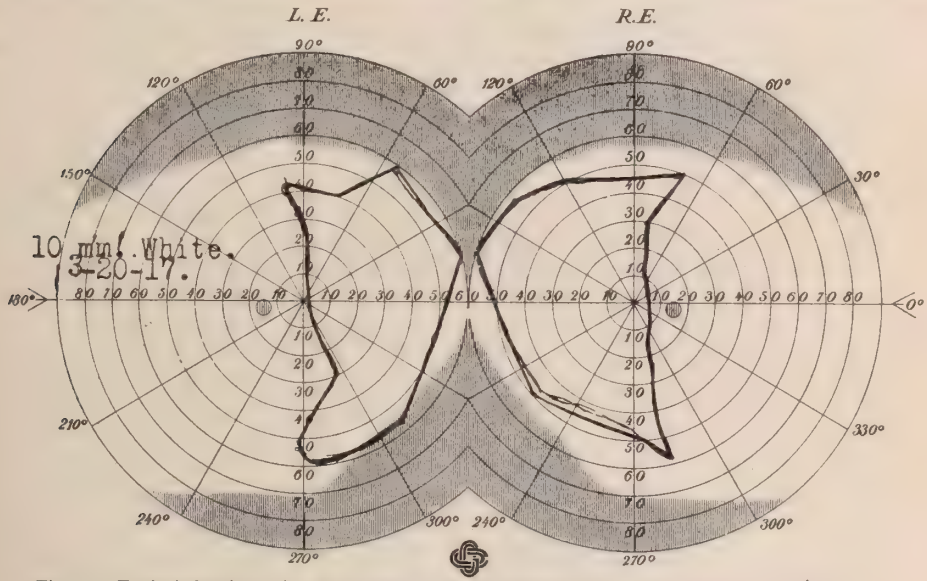

Fig. 1. Typical hemianopsia twenty days after operation upon the sinuses. (Conlon's case.)

could be seen postnasally after a treatment. The pain had now disappeared. Pupils were fully dilated and reacted feebly to intense illumination.

No limitations of ocular movements were at any time noted.

The patient was operated on by Dr. E. P. Emerson of Boston, on the first day of March, who did a submucous resection of the septum and an exenteration of both posterior ethmoids and sphenoids. An acute inflammation was found in both cells on each side.

The day following the operation the patient said he could see a white mist instead of the black one and could just make out the front of his bed, which appeared broken off in the middle. He now improved rapidly, so that on March 13th vision was 20/100 in each eye.

On March 20th, 1917, the fields were taken and the patient had a typical bitemporal hemianopsia with the dividing lines running nearly vertical, as will be seen on the chart. Fig. 1.

March 24th, 1917, Dr. Emerson removed a polyp from the region of the right ethmoid.

The fields remained unchanged until March 29th, when there was a noticeable improvement. Field increasing above and below. See figures 2 and 3.

The next few days the improvement was very rapid, so that on April 2nd the field for white was normal except for a large scotoma in each eye in the region of the blind spot. See figures 4 and 5. Color perception was lost absolutely for the following six or seven months, when there began a slow improvement. Recently the primary colors have been quite readily recognized but there is still a difficulty in matching shades, which has been the source of considerable embarrassment to the patient, who is engaged in the dry goods business.

11-19-18.—V., R. = 20/30 —.75 sph. = 20/15. L. 20/60 —1.00 sph. =20/20.

Both discs are greyish white. The pallor, however, is much more marked on the temporal halves. Fields tested with 5 mm. object show a concentric contraction of the form fields to roughly 40° in all meridians, the color fields showing corresponding narrowing with green within 5° of the fixation point.

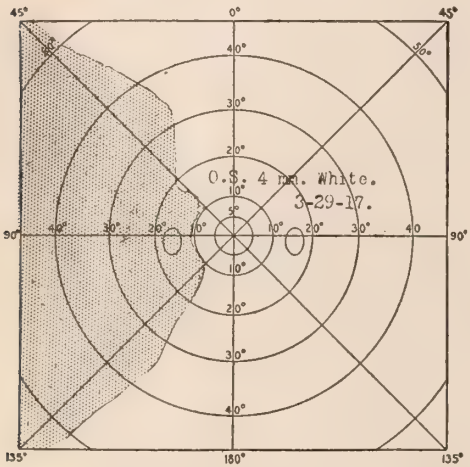

Fig. 2. Field of left eye nine days after Fig. 1.

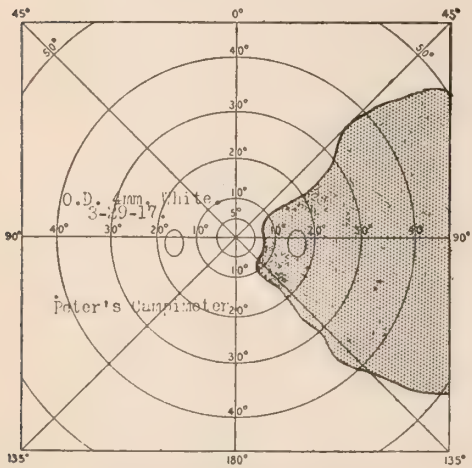

Fig. 3. Field of right eye nine days after Fig. 1.

There is still a slight enlargement of the blind spot, each one measuring about 10° in the horizontal diameter.

ANATOMY OF PARTS.

When we consider the extreme thinness of the bony wall separating the sphenoid from the optic canal, 38 per cent of which are extremely thin, measuring at times only ¼ mm., as has been shown by Francis and Gibson[7] in their careful examination of one hundred specimens; the unilateral or bilateral contraction of the temporal fields is quite easily understood as the fibers going to the nasal side of

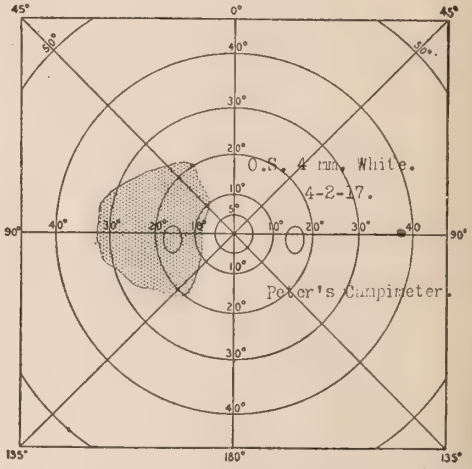

Fig. 4. Field of left eye four days after Fig. 2.

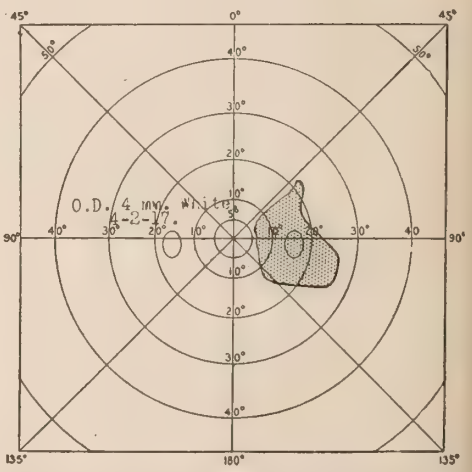

Fig. 5. Field of right eye four days after Fig. 3.

the retina are in contact with the lateral wall of the sphenoidal sinus while in the optic canal.

Onodi's[8] publications show that it is perfectly possible for a single sphenoid cavity to contain both optic nerves. So may it not be possible, and probable,

that a large number of the cases of neuritis and retrobulbar neuritis said to be due to influenza, measles, scarlet fever, diphtheria, and exposure to cold are due to sinuitis caused by the above mentioned diseases?

A well defined bitemporal hemianopsia, with the dividing lines running vertically thru or near the fixation point, is only to be explained by a lesion of the chiasm. The development of this condition is not so easily explained as it may appear at the first glance.

"The commissure or chiasm rests upon the optic groove of the sphenoid bone, being bounded, above, by the lamina cinerea; behind by the tuber cinereum and on either side by the anterior perforated space."

This expresses the general conception of its position, which is so stated in all the text books I have consulted, and brings to mind a remark frequently made by the late Prof. Dwight, who lectured on anatomy in Harvard Medical School. After the class had very industriously taken notes for twenty or thirty minutes he would suddenly bellow "That's what the books say, but it's not so at all; it's not so at all."

To begin with, the optic groove is not wide enough to hold the optic chiasm. Zander[10] found the groove to measure on an average 6 mm. anteroposteriorly while Lawrence[11] found a well developed one to measure 5 mm., and the chiasm was given by Zander as measuring 8.08 mm. and by Lawrence never less than 7 mm.

In fact the former investigator found no optic groove at all in 66 of the 100 skulls he examined, and never saw the chiasm as far forward as the optic groove, but found it lying from 4.75 mm. to 17 mm. posterior to it. The average distance was 16.34 mm. while the posterior edge projected on an average of 1.58 mm. behind the dorsum sellae.

Traquair[12-13-14] has repeatedly drawn attention to the true position of the chiasm and says that the usual description is completely imaginary, and not based in actual observation; and that if the chiasm with the apex of the third ventricle be left in situ after removal of the rest of the brain and viewed from above, a wedge-shaped portion of the diaphragma sellae, extending backwards to the extent of a third or a half, or even more of its antero-posterior diameter, will usually be seen in the angle between the optic nerves and frequently also a portion of the foramen diaphragmatis.

Bogoiavlensky[15] operating by the frontal route says that after lifting up the frontal lobe he saw in front of the optic chiasm a tumor occupying the entire space between the optic nerves. This would be manifestly impossible if the usual statement of its position were correct.

Here then is another case where the exception proves the rule, and I have been able to find among the numerous publications of Onodi one plate showing the relationship as it must exist in my case. Loeb[9] has given us another. In both the left sphenoid sinus is seen in close contact with the chiasm and occupying the entire space between the optic nerves.

As we have shown this close relationship of the sphenoid sinus to the optic chiasm to be the rare exception, rather than the usual arrangement, we can now explain the possibility of its occurrence and at the same time understand the comparative immunity of the chiasm to retrobulbar neuritis so commonly associated with postnasal suppuration.

MONOCULAR RETROBULBAR OPTIC NEURITIS FROM HYPERPLASIA OF THE ETHMOID BONE. REPORT OF THREE CASES WITH OPERATION.

Derrick T. Vail, M. D., F. A. C. S.

CINCINNATI, OHIO.

This paper by review of the pathology of the parts and the report of three cases emphasizes the connection of monocular optic neuritis and ethmoidal disease, and makes a plea for immediate operation in such cases. Read before the American Academy of Ophthalmology and Oto-laryngology, August 6th, 1918.

Hyperplasia is defined as an increase of the fibrous connective tissue elements of living anatomic structures, due to a low grade of localized inflammation. Delafield and Prudden[1] state "it is associated with long continued hyperemia or chronic congestion of the organ involved." Hyperplasia is a nonsuppurative process. Skillern[2] has demonstrated by means of many beautiful slides the microscopic difference between hyperplastic and suppurative ethmoiditis, before the American Laryngological, Rhinological and Otological Society. Beck[3] has also shown slides prepared from hyperplasia of the ethmoid bone.

Welsh[4] noticed "that the connective tissue stroma of an ethmoid specimen was thickened by fibrous tissue production and acute inflammatory products, and that there was thrombosis of many small veins." Shambaugh[5] recognizes the chronic ethmoiditis which is "primarily a nonsuppurative disease, but with impaired drainage of the cells due to hypertrophy of the mucous membrane of the cell walls." He calls the process hypertrophy, but hyperplasia seems to be the better term. Hypertrophy is defined by Delafield and Prudden[6] as "a simple increase of the *size* of the elementary structures of a part, usually associated with increased function of that part, while hyperplasia is an increase of the *number* of the elementary parts."

Hyperplasia of the ethmoid bone is a rarefying osteitis associated with inflammatory swelling and fibrous thickening of the mucous membrane lining its cavities, causing edematous tissue to fill them without the formation of pus. Its limiting wall (called the capsule), is also thickened and the entire organ is enlarged so that the orbital wall is involved as well as the nasal.

Owing to the fact that the middle turbinated bone is attached to the body of the ethmoid by a very narrow strip, this hyperplasia may be and usually is confined largely or entirely to the structure of the ethmoid proper; and rarely extends across the isthmus of bone to involve the middle turbinate itself. Because of this fact it is usually impossible to diagnose hyperplasia of the ethmoid by simple inspection.

Hyperplasia of the ethmoid bone is of itself a comparatively trivial disease. The nasal symptoms are not particularly distressing, for in spite of the sneezing followed by the watery discharge, transitory impairment of nasal

respiration and the paroxysmal reflex cough, the patient is not greatly annoyed. He may complain of being sensitive to drafts and subject to head colds, and also of being kept awake some at nights by having one side of his nose stopped up, requiring him to turn over on the other side. There is no pain, no purulent discharge and no impairment of the sense of smell.

Owing to the location and structure of the ethmoid bone and the truly remarkable variation in the size and arrangement of its pneumatic spaces, and also the fact that the optic foramen lies in many instances in juxtaposition to its large posterior cell (indeed may traverse it), hyperplastic inflammation may here assume an important role and produce blindness by causing retrobulbar optic neuritis.

The object of this paper is to establish clearly the relation between hyperplasia of the ethmoid bone and acute retrobulbar optic neuritis and to point out the importance of early diagnosis and early operation.

The ocular symptoms of inflammation of that part of the optic nerve which traverses the optic foramen (or what is better termed "the optic canal," for it averages 15 mm. in length), are definite and easily recognized. The patient complains of foggy vision affecting one eye, which rather rapidly becomes worse, so that in a few days he may be entirely blind in the eye. There is usually slight pain on directing his eye to the limit of motion; and a slight pain or uneasiness referred to the temple on that side and back of the eyeball. The one symptom which impels him to seek the ophthalmologist is the very positive and annoying loss of vision affecting one eye and the fear of blindness. There are no nasal symptoms and hence the rhinologist will not be sought.

In the fulminating type of the disease there will appear sudden severe pain, involving all the branches of the fifth nerve, particularly the filaments of the first division; and with it will occur blurred vision which *in a few hours progresses to total blindness of the affected eye.*

The objective findings which establish the diagnosis are of two kinds, positive and negative.

The positive findings are:

(a) Monocular blindness.

(b) Sluggish response of pupil to direct test.

(c) Dull pain on deep pressure.

(a) Monocular blindness: When there is vision present it is always eccentric. The periphery may still be normal with a very large total scotoma occupying the central area, as shown by the accompanying field charts of my cases. The scotoma is probably relative before it becomes positive; so that if the case appears early enough we would find a partial scotoma for colors in the center, with enlargement of the blind spot. When the patient comes later, as is usually the case, the blind spot is included in the scotoma.

(b) Sluggishly reacting pupil in the affected eye: This slow reaction of the pupil is present to the direct test and not to the indirect or associated tests. The pupils are usually of equal size, because the pathway of the third nerve down from the sphincter nucleus of the brain to the iris is not involved, and the light impulse in the unaffected eye causes an equal efferent response in both pupils. The pupillomotor fibers of the optic nerve in the affected eye are inhibited in function by the disease present in the optic nerve at the apex of the orbit; and hence tardily convey the light impulse upward to the brain, or not at all, as the case may be.

(c) Slight tenderness referred to the apex of the orbit when making pressure against the eyeball thru the closed eyelids: This symptom is not always present.

The negative findings are quite important for they assist greatly in establishing a diagnosis. They must be studied in relation to the positive. They are:

(a) Normal disc and fundus.

(b) Normal middle turbinate.

(a) Normal appearing optic disc and fundus in the eye affected with central scotoma or blindness is very characteristic of this disease. Later on, usually

after a month following the onset of the trouble, there will appear beginning atrophy of the optic disk. This atrophy progresses in proportion to the severity of the retrobulbar neuritis that preceded it and may be complete. Usually it is partial. A careful study of its extent will reveal that it involves the temporal side of the disc representing a wedge or a sector of from one-fourth to two-thirds of that side of the disc; and is a white atrophy with clearly cut disc margin; in other words, a typical primary descending atrophy. A small sector of the disc on the nasal side may still retain a degree of pinkness.

(b) Normal appearing middle turbinate body with no discharge present in the nose: The turbinate is usually not visibly enlarged nor is it discolored. It is not usually impacted against the septum, and there appears ample breathing space and normal nasal function. If, however, the body of the middle turbinate be shrunken, with cocain and adrenalin, one may find the evidence of hyperplasia of the ethmoid proper by observing small polypi hidden under it.

The differential diagnosis includes toxic amblyopia, congenital amblyopia, malingering, hysterical blindness of one eye, monocular optic neuritis from systemic infections and monocular blindness from fracture at the base.

In toxic amblyopia the history of inordinate use of alcohol and tobacco is usually easily determined or the taking of wood alcohol, large doses of quinin, etc., is admitted. Toxic amblyopia is much slower in its course than amblyopia due to ethmoid disease; moreover it is almost invariably expressed in both eyes, altho with different degrees of severity.

In congenital amblyopia affecting one eye the differential diagnosis is easily made, if the patient has been aware of affected vision in one eye for a long period of time. Occasionally such patients discover the amblyopia by accident only a short time before consulting the ophthalmologist, or the latter may discover it for the first time during the process of examination of the patient's sight. The cases of congenital amblyopia will show no central scotoma even by use of the 3 mm. disc. His fields of vision for white and colors will be normal in periphery and center. Congenital amblyopia is stationary and presents no sign of atrophy at any time, while the disease under discussion is never stationary and the disc eventually shows distinct atrophy.

Malingering blindness of one eye will be discovered by an astute ophthalmologist who knows how to conduct the proper tests and uses them.

Hysterical blindness in one eye is either partial or complete; if partial the field of vision is usually typically contracted with no evidence of central scotoma. If total the tests applied for detection of malingering blindness will suffice.

Monocular optic neuritis from system infection or disease, is diagnosed by the absence of central scotoma and the history of such infection, e. g., measles, typhoid fever, scarlet fever, etc. In some cases the optic neuritis and neuroretinitis are discovered to be due to albuminuria or diabetes, which may produce the same picture as infections. The optic neuritis due to local infections from showers of germs thrown into the circulation from a suppurative focus in the body as from diseased tonsils, diseased bone as at the apices of the teeth, etc., is differentiated also by the absence of central scotoma or rapidly progressing blindness and by the presence of a frank neuroretinitis.

It is sometimes difficult to locate the origin of these infections. One of the cases reported in this paper had an acute empyema of the ethmoid cells which produced no nasal symptoms worthy of note and which was discovered at the time of the operation. An able X-rayist must be engaged to make careful plates and submit them along with his interpretation. Other types of optic neuritis such as occur in brain tumor with increased cerebral pressure or from pituitary disease or meningitis, etc., need not be dwelt on here.

The type of optic nerve lesion which most nearly simulates that due to hyperplasia of the ethmoid is the trau-

matic, where there was a fracture of the base involving the bony structure at or near the apex of the orbit. I have seen recently a case where the X-ray showed a line of fracture involving the roof of the orbit running back to the bony apex, due to a fall into an excavated pit, the patient striking the right temple on a block of cement. There was total blindness of the right eye. Normal optic disc and retina were observed ten days after the accident. Signs of atrophy appeared on the twenty-first day and total atrophy on the twenty-eighth day, the eye remaining blind. In this case there was not the slightest sign of optic neuritis as seen with the ophthalmoscope. The atrophy was descending and primary, evidently due to compression from hemorrhage or swelling at the optic foramen, and was, practically speaking, the same kind of atrophy as seen in two of my cases due to hyperplasia of the ethmoid bone, which are reported in this paper later on.

Since hyperplasia of the ethmoid bone is a very common affection why is it that retrobulbar optic neuritis and consequent monocular blindness are so infrequent? The answer must be found in the aberrant anatomic arrangement of the posterior ethmoid cells, in relation to the optic nerve in the affected cases and not in others. Loeb and others have shown by wet specimens that the optic canal occasionally lies so close to the posterior ethmoid cells as to have a common wall between them; and that, too, of the thinness of paper. Indeed the optic nerve may traverse the posterior ethmoid cell and lie free in it for the distance of 12 to 15 mm.

The posterior ethmoid cavity of one side may be so large as to extend across to the opposite side and lie in relation to both optic nerves, which is also true of one of the sphenoid cells in other cases. The posterior cavity of the ethmoid is found more frequently in relation to the optic canal than is the sphenoid, altho it is true that the sphenoid and not the posterior ethmoid may lie next to the optic canal. Nature has not only created widely differing cell arrangements in the nasal architecture of different individuals but has jumbled the arrangement in the two sides of the same individual.

In case of periostitis, traumatism, hemorrhage or swelling of the walls of the optic canal, there is no provision of nature to guard the optic nerve against compression and strangulation. The optic nerve extends beyond the optic foramen within the skull cavity for a distance of 15 mm. before it reaches the chiasm, so that the compression of the nerve in its foramen does not affect the chiasm and the clinical manifestations are monocular.

The fibers which supply the macula lutea of the retina lie in the center of the optic nerve at the foramen; but as the eyeball is approached from behind they are seen to shift gradually toward the temple side, so that where the disc is seen with the ophthalmoscope they occupy the wedgeshaped temple fourth or third, and the artery and vein are at the center.

Why is it that the ophthalmoscopic examination is negative in the active stage of this disease? The answer is that the central artery of the retina and its vein only exist in the nerve for a distance of 15 mm. behind the eyeball. Beyond that they lie outside the sheath of the nerve. The transverse optic neuritis and compression exists nearly an inch further back and the retinal circulation is not impeded by it. Within thirty days after the disease announces itself atrophy of the disc is seen and it appears as a primary atrophy.

Why is central scotoma an early sign of the disease?

The papillo-macular fibers of the optic nerve are the finest, most highly specialized and most vulnerable. Swelling of the bony wall of the optic foramen causes as much pressure in the center of the nerve contained therein as at the periphery; this according to the well-known law of physics and the first to suffer are these delicate fibers supplying the macular region of the retina. It is not inconsistent with the theory of compression to have interstitial neuritis as described by Collins and Mayou, intraneural exudation, perineuritis, varicosity of the axis cyl-

inders, fatty degeneration of the nerve cells, capillary thrombosis, etc.; but I take it that these phenomena are secondary to the strangulation and are natural in pathologic sequence. They follow after the compression and in turn are followed by the atrophy. The point I wish to emphasize is that infection of the nerve is not necessary to produce optic neuritis within the optic canal. Mechanical pressure is sufficient. It is undeniable, however, that in certain cases the optic nerve may share in the localized inflammation because of mere identity of its bony collar with the ethmoid wall.

Arnold Knapp[7] recognizes the types of cases reported in this paper, stating there is retrobulbar optic neuritis in which central scotoma is the characteristic functional defect. He further states,[8] "Optic neuritis of nasal origin occurs in two forms: One during the course of suppurative sinuitis, the other where there is a typical retrobulbar neuritis and the rhinoscopic examination is negative. In the latter cases exploratory operation reveals a latent infection. The more acute the case the more rapid the loss of vision and the better the prognosis. The effect of the nasal operation is remarkable. The nasal diagnosis in these acute cases is often difficult; even with negative rhinoscopic findings an exploratory operation must frequently be undertaken."

Since my paper on "Optic Ne of is ial from Intranasal Disease," read b cen ue this society in 1901, I have 3 nt or many cases illustrating the relatio aite een tween ethmoiditis and acute ery how bulbar neuritis but I shall report t s of typical cases that came under my servation within three weeks of each other. All three were operated on at once in spite of the fact that in each of them the ethmoid appeared normal as viewed rhinoscopically.

CASES.

Case I.—L. W. E., male, age 35, occupation telegraph operator.

March 14, 1917.—*History*—Twelve days ago, while working in his office, he noticed foggy vision in his right eye. No pain was felt at any time. No history of trauma. Patient noticed deterioration of vision from day to day. Is a total abstainer from alcohol, tobacco and coffee. Denies syphilis. No nasal symtoms.

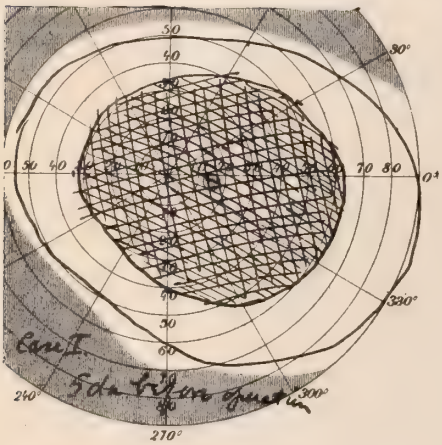

Fig. 1. Central scotoma in Case I. (Vail.)

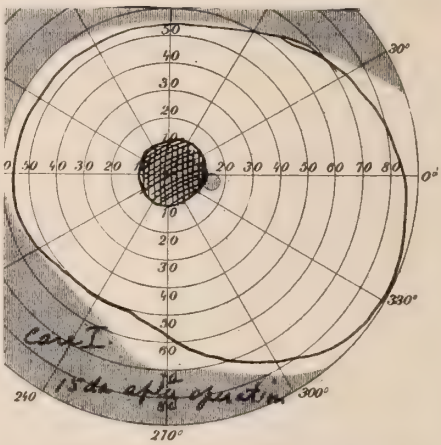

Fig. 2. Field in Case I two weeks after operation on the ethmoid.

Examination—Eyes: External inspection and tension normal right and left. Pupils 3 mm. right and left. Right pupil responds feebly to direct test and readily to indirect. The left pupil reacts quickly to direct tests and not at all to indirect. Ocular motility unaffected. Vision: Right eye cannot count fingers. Left eye vision 20/20 corrected and reads Ja. 1. Field of vision R. E.: periphery nearly normal; there is a large central scotoma extending approximately 40° in

all directions from the center. (See Fig. 1.)

Examination of eyes under homatropin: Pupils dilate equally and *ad maximum*, dioptric media clear. Fundus in each eye *appears entirely normal in every regard* and no difference noted by comparing the optic discs.

Nose: Inspection negative. Turbinated bodies appear unaffected, breathing space normal, no discharge

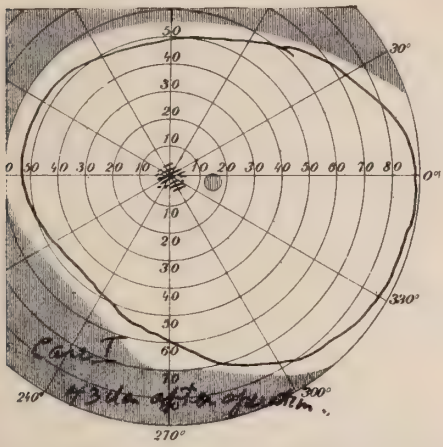

Fig. 3. Field of vision in Case I one month after Fig. 2.

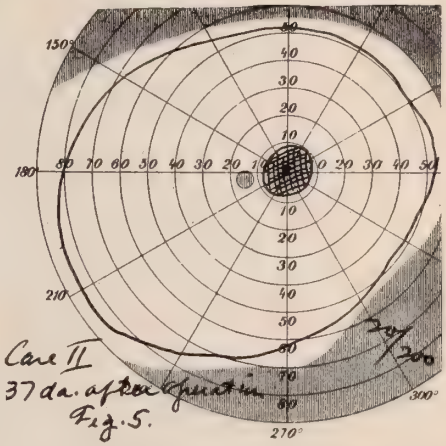

Fig. 5. Field of vision in Case II thirty-seven days after operation.

present and no difference noted between the two nasal chambers.

Report of Radiographer (Dr. Lange): "Frontals and antra clear. Oblique exposure of the ethmoid shows distinct clouding of posterior ethmoid cells on the right side. Sella turcica normal."

Diagnosis: Monocular blindness from nonsuppurative ethmoidal disease on the right side.

Operation: March 19, 1917. The right ethmoidal labyrinth was exenterated by Mosher's technic. Twenty-four hours after operation patient stated his vision was improved.

April 3; vision was 20/50 and central scotoma does not extend over 10°, from fixation point. (See Fig. 2.)

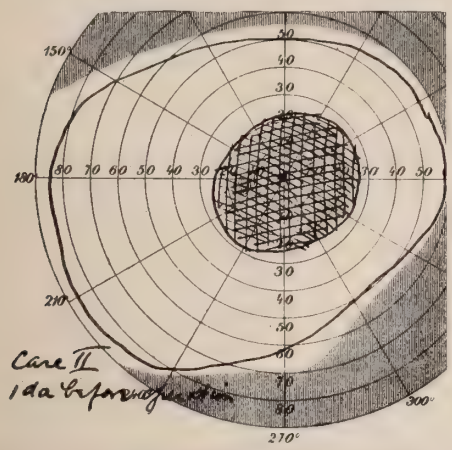

Fig. 4. Field showing central scotoma in Case II, one day before operation.

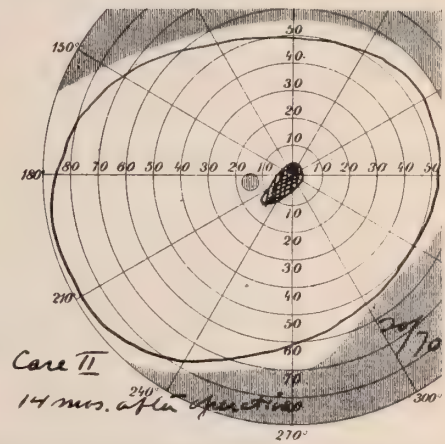

Fig. 6. Field of vision in Case II fourteen months after operation.

April 17; vision 20/30.

May 1; vision 20/30. Central scotoma is relative now and there are signs of slight atrophy on the temple side of the disc. (See Fig. 3.)

May 29, 1918 (one year later); vision 20/20 and reads Ja. No. 1. Oph-

thalmoscope reveals distinct pallor of the disc especially involving the temple side. Right disc is nearly white, left is quite rosy. In spite of the atrophy the vision is 20/20 and Ja. No. 1, and the fields of vision are entirely normal for white and colors. There was never any discharge from the nose after the operation and the operated field is clean and normal appearing.

Case II.—Miss V. M. Age 18—Occupation school teacher.

March 20, 1917.—*History*—Two weeks ago had a mild attack of "pink-eye" and "cold in the head." There was some pain in the left eyeball whenever she directed the eyes to extreme field of fixation. This pain still persists. Five

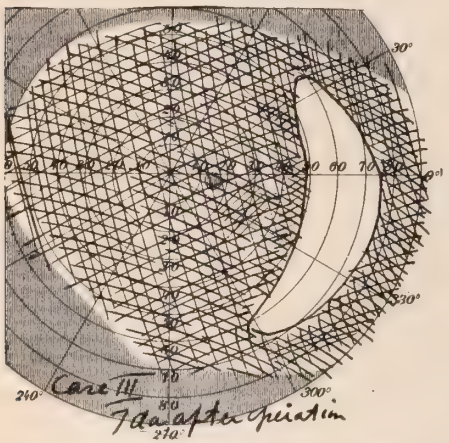

Fig. 7. Field of vision in Case III one week after operation.

days ago the vision of the left eye became dim.

Examination—Eyes: Right eye appears normal, pupil 2½ mm. and responds to direct test. Vision in this eye is 20/20 and Ja. No. 1. Field of vision for white and color normal right eye. The ophthalmoscopic examination reveals normal disk and fundus.

Left eye: Orbital tenderness on deep pressure against the eyeball. Pupil 2½ mm. and sluggish in reaction. Tension normal, ophthalmoscopic examination reveals a distinctly swollen optic disc. Veins are swollen and tortuous. Details of fundus quite hazy, due to presence of neuro-retinitis. Vision barely 20/200. Field of vision at periphery normal, but there is a large absolute central scotoma present. (See Fig. 4.)

Nose: Ample breathing space. Turbinated bodies appear normal and alike on the two sides. No secretion present.

Report of Radiographer (Dr. Lange): "Frontals and antra clear. The left ethmoid taken by oblique exposure shows distinct cloudiness. The right appears normal."

Diagnosis: Left optic neuritis from ethmoid disease.

Operation: March 21 a complete exenteration of the left ethmoid and sphenoid was done under cocain anesthesia. Cells contained pus.

March 24; the left optic disc appears less swollen.

April 7; can barely see 20/200. There are signs of beginning atrophy of the disc.

April 27; the left optic neuritis has subsided and atrophy is becoming established. Still has absolute central scotoma, tho not so large as at first noted. (See Fig. 5.) Vision now 20/200.

June 22; partial atrophy of the optic nerve especially noted on the temple side of the disc. Vision 20/100. Nose appears free from discharge now. The day following nasal operation there was quite a flow of creamy pus from the sphenoid and ethmoid region.

May 18, 1918 (14 months after); the right optic disc is normal and vision is 20/20 and Ja. 1. The left disc is uniformly pale. Small central scotoma (see Fig. 6). Vision 20/70. Nose free from discharge and appears healthy.

Comment.—This was undoubtedly a case of optic neuritis from ethmoid disease, as there was a suppurative process at work in the post. ethmoidal and sphenoidal cells. The rhinoscopic examination before operation could not detect the suppuration. It was revealed by the operation.

Case III.—Miss M. S. Age 60. No occupation.

May 4, 1917.—*History*—Without previous warning and from unknown cause the right eye suddenly became blind three weeks ago. The only other sensation was

that of a dull pain in the right temple and brow. The blindness of the R. E. is complete as there is no l. p.

Examination.—Eyes: External inspection negative. Pupils nearly equal in size. (R. 4 mm., L. 3.5 mm.) The right does not respond to light but it does respond consensually and associately. Eyes appear straight and motility is normal.

Ophthalmoscopic examination is entirely negative right and left. Vision, right, *nil*, left 20/20 corrected, tension normal in each eye, field of vision left eye normal for white and colors.

Nose: Nasal chambers appear entirely normal. No history of chronic nasal disease.

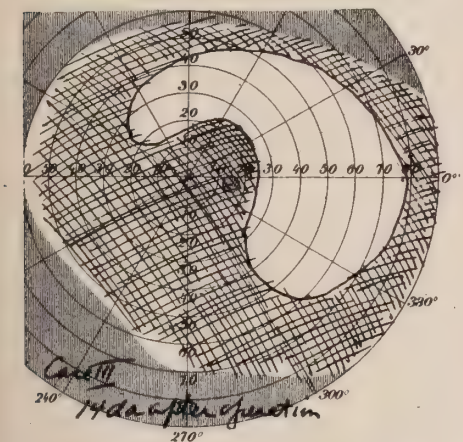

Fig. 8. Field of vision in Case III two weeks after operation.

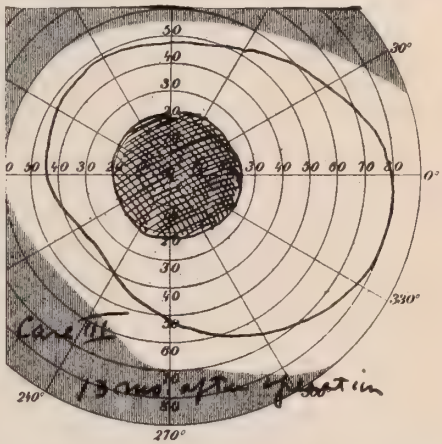

Fig. 9. Field of vision in Case III thirteen months after operation.

Diagnosis: Monocular blindness from concealed ethmoid disease.

Operation: May 4, 1917. Exenteration of ethmoidal labyrinth and opening of sphenoidal cell on the right side.

May 11; there is a slight response of pupil to light, and detects hand movements in extreme temple field. (See Fig. 7.)

May 18; can count fingers eccentrically. Still has central scotoma. (See Fig. 8.)

June 15, 1918 (thirteen months after); optic disc atrophied on the temple side. There is still an absolute central scotoma present as shown on accompanying chart (see Fig. 9), but the peripheral field is restored. Pupils are normal in size and the right now responds readily to light. The nose appears normal, no purulent discharge was present at any time before or since operation.

Vision: Can count fingers at 10 feet by eccentric fixation.

CONCLUSIONS.

The cases reported illustrate two types of monocular optic neuritis from ethmoidal disease. In the one type illustrated in Case No. II there was a frank exudative neuroretinitis, associated with functional blindness in the center of the visual field due to a suppurative process at work in the posterior accessory sinuses of the nose that lie in proximity to the optic nerve. The exudation was doubtlessly due to bacterial influences and the central scotoma to the swelling of the nerve (interstitial neuritis), within the bony optic canal.

In the other type illustrated in Cases No. I and III there was no bacterial invasion of the nerve present, but there was swelling of the orbital wall of the posterior ethmoidal or sphenoidal cell which pressed the optic nerve in its passage through the optic foramen and caused a strangulation of the nerve at this point. This compression no doubt produces a transverse optic neuritis which, while not due to bacterial invasion is nevertheless destructive to vision, and is followed by more or less permanent atrophy of the optic nerve. The nasal disease that produces this phenom-

enon is a nonsuppurative one, hyperplasia of the ethmoid bone.

The disease should be recognized and operation on the ethmoid performed at once in spite of its being normal in appearance. The diagnosis is made solely from ocular findings.

The plea I would finally make is *operate at once.* The prognosis is good as to restoration of vision if the operation is performed during the acute stage, but if delayed until atrophy sets in the prognosis is bad.

BIBLIOGRAPHY.

Since writing this paper Greenfield Sluder's book on *Headaches and Eye Disorders of Nasal Origin* (June, 1918, C. V. Mosby Co., St. Louis), has been published and we note many strikingly similar arguments to sustain the proposition that hyperplasia of the sphenoid and ethmoid bones causes visual and other disturbances from compression of the trunks of the anterior group of cranial nerves at the foramina of exit.

My paper was written without knowledge of Sluder's work in the same field, which accounts for lack of reference to his masterful production. His book covers a much wider range and, written by a rhinologist of renown, will receive and merit the highest commendation.

DISEASES OF THE UVEAL TRACT.

SAMUEL D. RISLEY, M. D.

PHILADELPHIA.

This paper gives a general review of certain important pathologic conditions affecting the uveal tract, especially tuberculosis and eyestrain; and of vascular changes that result from uveal lesions, notably myopia, glaucoma and cataract. Presented at the meeting of the special section of the Pennsylvania State Medical Society, Sept. 5th, 1918.

I have chosen among many possible topics for presentation in our special field of research, the diseases of the uveal tract and will discuss these disorders from the standpoint of etiology and their sequelae. No subject in ophthalmology could have been chosen which presents more features of dramatic interest or practical importance to every medical man. First of all, to epitomize my thesis, I need not remind you that the uveal tract of the eye is developed embryonically from the ectoderm and mesodern, and therefore is liable to participation in all of the systemic maladies which affect these tissues elsewhere in the organism; and, because of the anatomic conditions peculiar to the eye and their relation to the physiology of vision lead to a wide group of sequelae which seriously threaten to impair function. In the time I can reasonably take in presenting the subject, it will be impossible to trace the extended literature and I will, therefore, make only such reference as may be needed to emphasize my own conclusions based upon personal study.

My first appreciation of the signal importance of the uveal tract to comfortable physiologic vision was gained very early in my professional experience thru the careful clinical study of a large series of cases of recurrent iritis, the results being set forth in a paper entitled, "Iritis—A Clinical Study,"[1] presented to the Pennsylvania State Medical Society in 1877, and with greater elaboration in 1884 in a second paper entitled, "Recurrent Iritis."[2] About the same time the observations

were being made which led up to the examination of the school children's eyes in Philadelphia,[3] which was primarily an investigation to discover the genesis of the myopic eye. It soon became obvious that in iritis the inflammation did not involve the iris only, but the entire uveal tract; and that the distension or enlargement of the globe in myopia was not, as had been claimed a physiologic growth; or an adaptation of the eye to the requirements of civilized life, as had also been claimed; but was always associated with quite characteristic pathologic processes involving the uvea, especially the choroidal and ciliary regions of that membrane. In a word, myopia was a sequel to the uveal disease.

Incidentally, it was demonstrated by that investigation that the children having emmetropic eyes passed thru their school life with a minimum of pain and disease while the eye strain consequent upon congenital abnormalities of refraction and ocular imbalance resulted in pathologic states involving the uveal tract; were invariably associated with pain, and lowered sharpness of vision. This was especially true where hyperopic astigmatism was present; and that the percentage of these eyes steadily diminished as the age of the pupils advanced while the percentage of myopic eyes increased in a corresponding ratio. Briefly stated, the myopic eyes were recruited from the hyperopic eyes thru the turnstile of astigmatism and always thru the agency of the pathologic states of the uvea produced by eye strain. This conclusion was fortified by the publication of a series of private patients in which this change of refraction was observed during its progress under the most careful scrutiny.[4]

Then, too, I have had the opportunity to observe a hyperopia of 2 D. converted into a myopic refraction after a prolonged attack of severe iridochoroiditis where adhesions of the iris to the lens capsule had been prevented by treatment, and the lens remained clear. The myopia was therefore due to axial increase. The patient was a man aged forty-five with a marked tendency to rheumatoid arthritis. The iridochoroiditis was a distressingly painful experience and a tendency to increased tension of the globe had constantly to be combatted, the violent attacks of pain being relieved only by instillations of eserin. It is my frequent practice to use weak solutions of eserin salicylat at intervals between the instillation of atropin in the treatment of all uveal affections.

At first thought, the progressive myopia of youth and the glaucomatous eye of after middle life, are as far apart as the poles. But careful consideration will show that the relatively tender sclerotic of youth distends under the undue intraocular tension produced by the congested and inflamed vascular choroid and ciliary body in the presence of eye strain or disease and the diameters of the eyeball increase. In a word, it becomes myopic. On the other hand, the tough unyielding sclerotic of middle life in the presence of uveal disease, presents the painful and destructive syndrome of increased tension of the globe. In such a view we at once grasp the dramatic significance of disease of this vascular membrane in the life history of the eye. Composed as it is of a meshwork of connective tissue, pigment epithelium and blood vessels with their accompanying lymph spaces, it is the nourishing coat of the eye.

The well being, therefore, of all the other tissues is either wholly or in a large measure dependent upon the normal or healthful performance of its important function. Not only is this true of the different parts of the uveal tract itself, but it is peculiarly true of the avascular structures of the eye; the vitreous body; the crystalline lens; and the cornea. I know of no more important or inspiring study to the thoughtful ophthalmic surgeon than the careful perusal of one or more of the later books devoted to the investigation by modern laboratory methods, of the anatomy and histology of the human eye. The studies of the histologic anatomy of the ciliary body and ciliary processes and their relation to the zone of Zinn, the suspensory ligament, the

anterior limiting membrane of the vitreous body, the scleral ring and root of the iris are especially important if one is to have a correct concept of the processes of disease of the uveal tract, or for the adoption of scientific procedures in their treatment.

The zone of Zinn, and the suspensory ligament of the lens are not to be regarded as impervious, glass like membranes, but as finely fibrillated structures and therefore pervious to the nutritive fluids from the choroid and ciliary region of the uvea designed as they pass forward not only for the nourishment of the vitreous, lens and cornea, but into the anterior chamber for exit into the canal of Schlemm and the lymph spaces of the conjunctiva. From this anatomic and histologic arrangement it is obvious that any disturbance of these delicate and highly organized structures by disease of the uvea must be of signal importance as a disturbing factor in the nutrition of the eye. Then, too, it is highly probable that the nutritive fluids secreted by the uvea are changed in character when that membrane is subject to toxic inflammation.

There is probably no organ in the body more prone, than the uvea, because of its highly vascular character, to participate in a large group of systemic disorders of the nutritional type; the toxemias and infections. In a word, all the affections of the cardiovascular system in which the kidneys are so uniformly involved, are, I think, quite as liable to have associated disease of the choroid. Not necessarily because of the nephritis, but for the reason that the choroid and retina, and the kidneys have in common become involved in the general disorder. In chronic rheumatism, gout, arthritis deformans, glycosuria, etc., with the phenomena of increasesd blood pressure, and arterial sclerosis, it is comparatively rare not to find associated disease of the retina and uveal tract.

The high arterial tension, the hypertrophied left ventricle, the chronic nephritis, apoplexies, angina, present a picture of serious systemic disease which the ophthalmologist unfortunately is all too frequently called upon to witness, because of the associated ocular conditions. It is not reasonable to suppose that the blood vessel system of the eye would escape from participation in the disaster which has fallen with such serious consequences upon the general vascular tree.

Indeed, the ophthalmic surgeon is, not infrequently, the first to detect the insidious approach of the general disorder, since the dioptric system of the eye enables him to study the intraocular tissues under an enlargement of approximately fourteen diameters, and so affords a unique and favorable opportunity to study the pathologic change going on in living structures.

It is under these conditions that he observes the veiling of the fundus details by edema of the retina and choroid in autotoxemia; the innumerable small apoplexies in hemorrhagic retinitis accompanying the later stages of nephritis; in perivasculitis and endarteritis; conditions which so frequently culminate in increased tension of the globe or even in the violent and fatal syndrome of hemorrhagic glaucoma. Indeed, it not infrequently happens that these eye conditions are only the culmination of blood vessel change which has been insidiously progressing, *pari passu,* with that in the general blood vessel system.

This is not the time or place; indeed before this Section it is not necessary to enter upon the etiologic factors in the general or systemic disorders of the nutritional and toxic type. It is my wish only to urge the recognition of the important fact that the uveal tract of the eye may and usually does participate in the general misfortune. In a word, they must be considered as etiologic factors in choroidal disease. The ophthalmologist must first be a physician.

In addition to this important group must be considered the infections: rheumatism, syphilis and tuberculosis as etiologic factors which are always in evidence. Rheumatism and syphilis as the most frequent causes of iritis, iridocyclitis and iridochoroiditis we have long recognized; but I believe the sig-

nal importance of tuberculosis as a frequent cause of these inflammations of the uveal tract has not been adequately appreciated, certainly not until within comparatively recent years. Did time permit, a large amount of clinical material could be brought forward to emphasize its importance. Of late years in rebellious cases of uveal diseases at the Wills Hospital Clinic, and in my private work, the von Pirquet test has been made as a routine procedure, in many instances causing not only local reaction but a rise of temperature. In a large percentage of these patients, recovery was so rapid under the subsequent injections of steadily ascending doses of old tuberculin as to excite one's enthusiasm.

UVEAL TUBERCULOSIS

For example, I relate the following case: A large rosy cheeked Italian fruit dealer, came to the clinic with violent pain from an acute increase of tension in the left eye. He was admitted to the wards and placed under treatment until the subsidence of the acute attack. A peripheral iridectomy was then performed, which promptly relieved the tension and pain, but the convalescence was prolonged. The tension was normal but the eye remained red and uncomfortable, and vision did not improve. After two weeks, a gray, discreet deposit was discovered on the cornea in the anterior chamber near the temporal angle of the coloboma left by the iridectomy. It suggested a tubercular deposit. The von Pirquet test was made and was followed by a marked reaction at the site of the test on his arm, and by marked focal reaction in the eye, and a rise in temperature. When this subsided the eye began a rapid recovery. The usual injections of old tuberculin were administered under which the eye became white, the nest of deposit in the cornea disappeared and ophthalmoscopic study of the fundus became possible. There was a deeply cupped nerve and numerous splotches in his choroid, far forward in the ophthalmoscopic field, presumably the site of tubercular infections or deposits. After the iridectomy the infection had passed through the coloboma into the anterior chamber and formed a nest of deposit on the cornea.

It is probable that in many instances the choroidal patches which are so characteristic of *choroiditis disseminata* are of this nature. A lady, a private patient, who had suffered for a long time from ill health which baffled her physician, and who had received from me glasses correcting a refraction error, but at that time with entirely healthy eye grounds and normal acuity of vision in each eye, came to the office a few months later in great alarm over the loss of vision in her right eye which came on, she said, during the preceding night. In the left eye V=6/v, but in the right it had fallen to 1/v.

The ophthalmoscope revealed in the nasal fundus a large gray area of edema, the retina being pressed forward, and opaque, but at the center of the gray area at its most prominent point the electric ophthalmoscope showed a dense white spot. The tension of the ball was not increased. The von Pirquet test was made and proved positive causing very slight, if any, ocular reaction. The rising doses of old tuberculin led to a rapid subsidence of the infiltration and a marked improvement in her general health. Vision rose once more to 6/v, but at the site of the tubercular deposit in the eye ground there remained a patch of choroidal atrophy such as are so frequently seen in disseminated choroiditis. No other nodules or yellowish spots were discovered; it was not therefore, of the miliary type which is more common especially in young children.

I have, in many cases of disseminated choroidal patches, with progressive loss of vision and pain in the eyes and head, seen the process arrested by the administration of old tuberculin. Tuberculosis, must therefore, be regarded as one of the more common causes of disease of the uveal tract. Coming under the same category are many cases of keratitis, which show grayish discreet nests of tubercular deposit on the membrane of Descemet, often near the angle of the anterior chamber, or nodules on the anterior surface of the iris. In this connection it should be borne in mind that the mem-

brane of Descemet is embryonically the extension forward of the uveal tract.

To the ophthalmic surgeon these affections of the uvea, whatever may be their etiologic factors, are important, not only as local manifestations of disease, which it is our duty to treat; but because of their dire sequelae. Among these are first of all, the handicap which comes with impaired acuity of vision as in the myopic eye, from pathologic changes in the retina and choroid at the posterior pole, i. e., in the macular region. Second, degeneration of the vitreous body and opacity in the posterior capsule of the lens, and of the lens cortex and nucleus. Third, iritis and iridocyclitis with adhesion to the anterior capsule of the lens and between the root of the iris, the anterior prism of the ciliary body and scleral roll. Fourth, increased tension of the globe as sequel to impaired drainage caused by these plastic adhesions.

In a word, we find in the pathologic affections of the uvea the *fons et origo* of the most serious forms of ocular disease with which we must contend.

UVEITIS AND CATARACT

When a young student of ophthalmology, I followed the teaching and example of my instructors in regarding opacity of the crystalline lens, particularly hard cataract, as one of the concomitants of old age, in common with other senile changes. Patients with immature cataract were, therefore, advised of their misfortune but encouraged to wait with such courage and patience as they could command until the cataracts were "ripe" when their vision would be restored by removing the opaque lens. After the importance of errors of refraction as an etiologic factor in asthenopia and pathologic changes in the *fundus oculi* had been demonstrated in the school examination, and the subsequent experience based upon the inductions from that investigation, I began to treat all patients with uveal disease with cycloplegics. And where it was possible to do so, that is to say, if the opacity of the lens permitted, made careful records of fundus conditions, associated asthenopia, etc., and carefully corrected any existing error of refraction; and made a painstaking examination of systemic conditions. They were kept under observation by occasional return visits. Their comfort was often secured and vision improved. Finally, it became obvious that in many of these patients the opacity of the lens had not progressed; indeed, it was a rare exception for one of the cases so treated to return for extraction.

The case books were then appealed to for corroboration. Sixty cases were found in which the records were sufficiently full for analysis, and were made the basis of a paper on "Incipient Cataract—Its Etiology, Treatment and Prognosis."[5] The results were of signal importance and value. The analysis demonstrated the invariable association of these incipient opacities of the lens with uveal disease and that when this was successfully treated the opacity did not advance and the acuity of vision often improved, but in no instance were the spicules of opacity already present observed to disappear, although the opalescence and swelling of the lens habitually grew less. Since the publication of that paper in 1869, the sixty cases have been increased many times over but the added experience has served only to emphasize the truth of the induction then made and stated in the following conclusions:

"In the stage of incipiency, cataract is amenable to treatment by such measures as are calculated to remove the choroidal disease upon which it depends.

"These deductions being true, we are justified in giving a more hopeful prognosis to many persons who apply for treatment with incipient cataract.

"If treatment fails to arrest the progressive degeneration of the lens, the eye will be in a better condition to submit to the trials of operative interference."

If these conclusions are accepted as true, then the designation, *"senile cataract"* is a misnomer and therefore, misleading. Furthermore, experience shows that aged people, who have cataract, are after all is said, the rare exception. It is only a fair deduction that in these exceptional cases there must be some peculiar condition present to cause their cataract. It is the contention of this paper that the impaired health of the eye consequent upon uveal disease had resulted in the

opacity of the avascular lens through disturbance of its nutrition.

THE MYOPIC EYE

In the preceding remarks, allusion has been made to increased tension produced by the congested or inflammed choroid leading to distention of the globe in early life, resulting in the myopic eye. This distention in young eyes is not always by any means confined to the posterior pole as in cases of progressive myopia with posterior staphylomata at the temporal side of the optic nerve entrance. There is usually an increase in all the diameters of the ball as well as in the antero-posterior axis. The objective syndrome is interesting and important.

In the presence of the uveal disease the long anterior ciliary vessels, as they course over the sclera in the anterior ciliary region, will be found engorged always suggesting uveal disease; and the sclera often obviously thin and distending. When the pupils are dilated the plane retinoscopic mirror will frequently reveal a granular ring concentric with the margin of the pupil; or a granular cloud in the illuminated pupillary area, which I regard as indicating the participation of the membrane of Descemet in the general uveal disease of the fundus, and indicates the beginning impairment of nutrition of the cornea. The ophthalmoscope shows a fluffy fundus throughout the ophthalmoscopic field, veiling all details.

It is in these cases we observe changes in the corneal astigmatism, either an increase of the astigmatism or a change in the direction of the meridians. These conditions are not confined to the eyes which have passed into myopic refraction, and are comparatively rarely seen in mature adults but are frequently present in young people suffering with asthenopia and portend increasing refraction. After prolonged use of a mydriatic and rest from near work, the fluffy fundus, the clouds in the cornea and the engorgement of the ciliary vessels disappear, while the asthenopia subsides.

UVEITIS AND GLAUCOMA.

In adults during middle life, the uveal disease associated, as it quite invariably is, with systemic affections, presents for consideration a very different group of phenomena. The dilated or engorged ciliary vessels are present, there is failing central vision and contracting fields; the tension of the ball is increased. In the early stage of the disease there may or may not be acute or subacute inflammatory attacks attended by increased pain and dim vision with diminished sensibility, with slight steaminess of the cornea and well marked increase of the tension.

With or without treatment the attack usually subsides and both the objective and subjective symptoms disappear, but there usually remains some increased impairment of function in both the central vision and the fields. After an interval, the attack is sure to return if suitable treatment is neglected. The marked similarity of this history of recurring attacks, to the history of recurrent iritis is obvious, barring the marked increased tension and contracting fields of vision which characterize the glaucomatous eye.

As in recurrent iritis, the succeeding attacks leave additional posterior synechiae at the pupillary margins, so in subacute glaucoma the attacks leave adhesions between the root or periphery of the iris and the anterior prism of the ciliary body and the scleral ring. I have had many opportunities to demonstrate these adhesions in eyes which have come to the laboratory for study after enucleation. Indeed, they are quite constantly present in all the eyes where increased tension had been an important feature in the recorded clinical history. In recurrent iritis, an iridectomy when accompanied by suitable systemic treatment arrests the disease, so in these cases of increased tension with adhesions at the root of the iris the recurring attacks are arrested.

It is the cutting free of these adhesions through a considerable arc at the base of the coloboma in a properly performed broad peripheral iridectomy that gives that procedure a greater value than trephining, which is quite valueless in the majority of cases unless accompanied by iridectomy, and this in any case can only be a very narrow one, thus freeing the adhesion in a very limited arc. It was partly upon these considerations that I

ventured to predict that the employment of the trephine did not meet the requirements as efficiently as a technically correct iridectomy. The theory promulgated for the trephining operation is that it establishes a permanent drainage and thus relieves the tension of the globe. But if we accept the thesis that the increased tension is a sequel of uveal disease it is obvious that the mere fact of drainage will not arrest the degenerative processes going on in the eye. I have seen many examples which seem to buttress the truth of this statement. In brief, the etiologic factors, systemic and local, underlying the uveal disease must be sought for and treated.

Increased tension of the globe assumes at once a wider significance when regarded as a symptom and sequel of disease affecting the choroidal tract and must modify in many important respects the views underlying our treatment. The term "glaucoma" falls from its place as an entity in our catalog of ocular diseases, and must be regarded by the ophthalmic surgeon as only "a convenient appellation" for an important characteristic symptom of ocular disease, but not the disease itself. The acceptance of this view has for many years modified my own concept of glaucoma and controlled my management of eyes with increased tension.

The failure to recognize its etiologic significance has doubtless led to the early adoption of surgical interference at a stage of the disease when other measures should have been first employed. By way of illustration, attention may be called to the great value of iridectomy in the treatment of chronic recurrent iritis, but no experienced surgeon would think of adopting this valuable surgical procedure during an acute exacerbation. The same consideration should be the guide to treatment in those cases of uveal disease with a cataractous lens or in which the increased tension of the globe is the dominant symptom. In short, it is obvious that the underlying etiologic factors both local and general, should be considered, and as far as possible removed by treatment before the adoption of any surgical procedure. The failure to do this, affords sufficient explanation for the unfortunate sequelae so frequently following either iridectomy or any of the more recently devised operations for the relief of increased tension. Notwithstanding the extensively published experience with these modern procedures, I am not convinced that the mere fact that permanent drainage has been secured through an opening at the sclero-corneal limbus is a cure for the diseased condition of the globe culminating in increased tension.

In no other form of ocular disease, inflammatory in character, has the ophthalmic surgeon been so prone to undertake operative procedure as in inflammatory glaucoma. This has seemed to be justified by the rapidly fatal results to vision if relief of high tension were delayed. But if the contention of this paper is true, the early recognition of the essential nature of the disease and the adoption of suitable methods of treatment will, in the vast majority of cases, prevent the violent culmination we all know so well.

ESERIN IN UVEAL DISEASE.

It is a well known fact that a very large percentage of the patients who apply for treatment with transient attacks of the symptom complex, designated as *"glaucoma imminens,"* are relieved by the instillation of miotics, aspecially eserin, and that operative measures are not required, if at the same time suitable attention is given to the underlying etilogic factors usually found in general systemic states. Many examples could be brought forward in which under treatment the fellow eye recovered without operation which had proved necessary to the other.

The problem to be solved, however, is a very different one, if the disease has advanced, either through neglect or in spite of treatment, to a stage where permanent pathologic changes in the intraocular membranes have impaired the nutritive functions of these membranes and the drainage channels of the globe have been more or less permanently blocked by connective tissue formation; when the ciliary body is undergoing atrophy and the contracting adhesions have dragged the root of the iris backward and in contact with the scleral ring. We are then,

in my judgment, no longer justified in trusting to the influence of miotics. When we come to consider the physiologic properties of the most efficient of the miotics, physostigmin or eserin, it will be seen why this statement is true.

In answer to an inquiry, "how or why does eserin relieve intraocular tension?" I recall two experiences which have afforded, to me at least, a satisfactory explanation. A young woman with a leucomatous cornea and a blind eye came to the clinic complaining of pain; the old leucoma which had been for years entirely white and free from irritation was vascular, the ball tender to palpation and with increased tension. A solution of eserin was instilled; and at the close of the clinic hour the blood vessels in the white cornea were no longer visible except with the loup; the pain had disappeared and the tension was normal. A short time after a young man presented himself for treatment, giving a vague history of discomfort, occasional attacks of redness in one eye. Inspection showed an arborescent arrangement of blood vessels over the anterior surface of the entire iris. Having in mind the speedy disappearance of the blood vessels after the instillation of eserin in the case narrated above, eserin was instilled and the patient received a solution to be used at home. On his return the following day, the vessels were no longer visible to the unaided eye. The effect of the eserin in these two cases was ascribed to its influence over the muscle fibres in the walls of the blood vessels.

At that time and even now there is much confusion over the physiologic properties of this drug, but all experiments seem to agree that the well known rise in blood pressure after the administration of eserin is brought about by the stimulation of the muscular coat of the arterioles; that physostigmin increases the irritability of both striped and unstriped muscles, even causing tetanoid contractions, the effect apparently being due to the stimulation of the peripheral nerve endings. Local applications, it is claimed cause marked contraction of the pupil by stimulating the peripheral endings of the ocular motor nerve and probably also the iris muscle itself and causing the spasm of the accommodation by acting similarly on the ciliary muscle.

Now if these observations are correct, eserin is useful in the conditions which have been described as characteristic of the glaucomatous eye by contracting the uniformly dilated ciliary vessels in all of their ramifications in the iris and ciliary region. In this manner the hyperemia would be reduced, the secretion diminished and the general turgescence of the swollen ciliary body and ciliary muscle relieved. The instillation of solutions of suitable strength frequently repeated should therefore, reasoning *a priori,* be of great service in the premonitory stages of increased tension and should hold in check the pathologic processes which culminate in increased tension of the ball. The mistake of using too strong solutions of eserin is often made. It should never cause pain, as this is an indication of muscular spasm or cramp; weak solutions frequently repeated are more useful and are often of great value in the treatment of iritic and ciliary inflammations in alternation with the mydriatics.

But where permanent changes have already occurred, while its use in some measure retards the progress, it is obvious it can not remove or permanently arrest the baneful influence of the permanent pathologic changes at the root of the iris at the scleral ring. The effect of these contracting adhesions between the anterior prism of the ciliary body, the root of the iris and the scleral ring is analogous to the irritating influence of synechia between the capsule and iris after the extraction of cataract, or anterior synechia after perforating ulcer of the cornea and in certain cases of iritic adhesions. It is a common experience that such eyes remain irritable and show a tendency to recurring attacks of inflammation, which subside after the release of the adhesion.

In like manner the tendency to irritation and recurring attacks of increased tension will not permanently subside until the contracting bands of adhesion between the ciliary body at the scleral ring and root of the iris are released. To accomplish this design I know of no procedure which will release these bands thru so considerable an arc of the peri-

phery of the iris as a correctly performed broad iridectomy. It is open to question whether the securing of a drainage wound is correct in principle. Iridectomy, however, should not be undertaken until by suitable local and general treatment the acute inflammatory manifestations have subsided, and this treatment after iridectomy should be continued until the uveal disease has recovered.

A NEW "MALINGEROSCOPE."

ELLICE M. ALGER, M. D.

NEW YORK.

With a discussion of the present need to discover malingering and ascertain as nearly as possible the actual vision of the eyes alleged to be amblyopic, this paper describes a new instrument for testing the vision of the alleged weak eye while the patient believes that he has seen with the other. The instrument was presented in a paper on Malingering at the annual meeting of the Medical Society of the State of New York, May 23, 1918. It can be obtained from F. A. Hardy & Co.

Visual malingering received but little practical attention from most American ophthalmologists till the passage of the Universal Service laws. The subject has, however, proved not to be so important from the military standpoint as was expected. There has been remarkably little persistent malingering, on the one hand, while on the other it is universally agreed that the persistent malingerer is of little military use. Apparently the officers of the army have often wasted more time and ingenuity in getting rid of these men than the local advisory boards did in getting them inducted.

If we are to judge by past experience, however, the subject may be of vastly greater importance when we begin to settle with the returning soldiers over their disabilities and pensions. It will be of even more importance in civil life because of the rapid and constant growth of accident insurance and industrial compensation. Ocular accidents capable of reducing vision outnumber all other accidents; while no type of injury causes, when real, greater reduction of earning capacity or makes a stronger appeal for sympathy and compensation. There is no kind of malingering which is harder to detect and to demonstrate.

In industrial work, at least, the detection of malingering is not the sole, or even the most important purpose of the examination, for there is no hard and fast line between exaggeration and malingering. The idea is to ascertain the exact organic and functional capacity of the eye, and the probable cause of any defect found. The success of the examination does not depend on any one or two classical tests but upon the ophthalmologist having a quick appreciation of what an eye ought to do under varying conditions, and on his ability to put the claimant rapidly into positions he has not anticipated, without rousing his suspicions or antagonism. The skill required is psychologic as much as ophthalmologic.

There are two different types of test for malingering; first, those intended to show merely that a supposedly blind eye has sight, and second, those tests which are capable of showing the degree of sight present. To the first class belong the pupillary reactions and many of the various diplopia tests. Their value is the less because they

would often be present in absolutely useless or dangerous eyes. Their chief function is to impugn the credibility and good faith of the claimant. Much more important are the methods which show in some degree the actual vision in each eye. These all depend on making the patient think he is seeing with his good eye when he must be using the poor one alone, and they all imply the apparent use of both eyes together. In this class come the tests involving the blocking out of the good eye by a strong convex glass, the bar reading tests, the various maneuvers possible with the stereoscope, the reading of colored letters thru colored glasses, and a few of the diplopia tests that appear in all our text books.

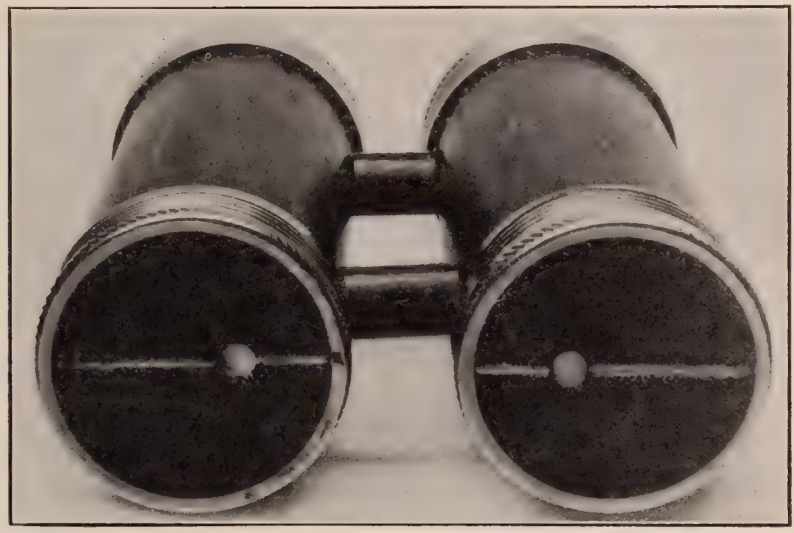

Fig. 1. Alger's new malingeroscope.

Like many other men who have been engaged in Local and Advisory Board work, I have experimented with various "malingeroscopes" and finally worked out the following one which in my hands has been more satisfactory than any single test. It is extremely simple, easily extemporized, and confuses even the very intelligent as to which eye is being used. Fig. 1.

It consists of two short parallel cylinders (four inches by one and one-half), arranged opera glass fashion. The distal end of each tube is covered by a cap which can be rotated, and contains a six mm. aperture, eccentrically placed. The caps can therefore be rotated so that the apertures, while in the same horizontal plane, may be as close to each other as 45 mm. (less than the average interpupillary distance), or any distance apart up to 70 mm. (more than the average).

The patient looks thru the instrument as he would an operaglass, at two ordinary test cards, twenty feet away, side by side, and about eighteen inches apart. The apertures are large enough to cover the width of one card but do not permit both to be seen at the same time with either eye alone. When the caps are so rotated that the distance between the apertures is nearly that between the pupils (Fig. 2, position 1), the right hand card is clearly visible to the right eye and the left hand card to the left eye (homonymous vision); but neither can see both cards at the same time. When the apertures are approximated slightly (Position 2), so as to permit slight convergence of the visual lines, both eyes see the same card simultaneously. When the apertures are approximated to considerably less than the interpupillary distance,

which is much the most useful arrangement (Position 3), both cards may be seen at the same time, but the right hand card is seen only with the left eye and vice versa (crossed vision). The sensation is that of binocular vision of both cards, but it is

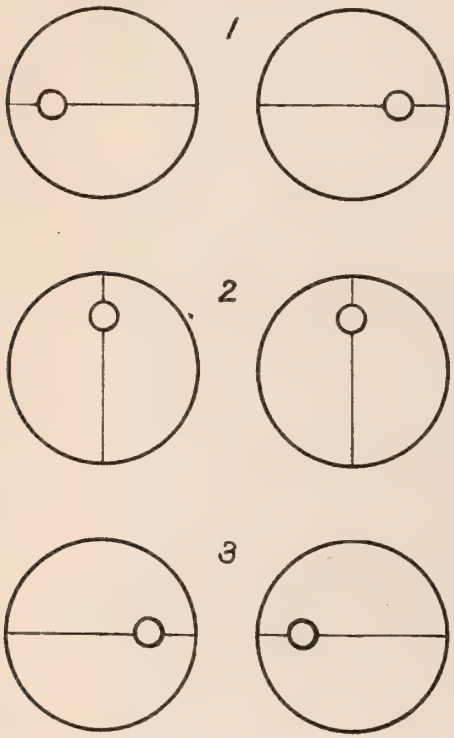

Fig. 2. Diagram showing various positions in which the apertures may be placed in using Alger's malingeroscope.

not quite that, for to read the right card the eyes have to be directed slightly to the right of the mid line, thus increasing the impression that one is using the right eye, while he is actually using the left, and vice versa.

As he looks thru one aperture at either card the image of the other aperture falls outside the macula of the fellow eye so that he is conscious of seeing two apertures and these apertures are "crossed," the apparent right one being actually before the left eye and vice versa. If the malingerer is asked to read the right hand card, thru the right hand hole he is apt to think he is using his right eye when he is really using his left. If he is told to read with his right eye, if that is the better one, and a card is held over the (to him) left aperture he assumes that he is really using his right eye and vice versa. In case there is a real difference in the vision of the two eyes, the intelligent patient can often readily tell which eye he is using, but as he has no means of knowing just how much he ought to see with the instrument it is easy enough to blur the vision of the better eye by holding a lens over the appropriate aperture and make him think he is using the better eye.

If two exactly similar charts are used, patients with strong fusion instincts will often fuse them by converging the eyes and see only one aperture and one card. If now extra letters are interpolated at different places on each card the patient will read them just as tho they were on both.

The instrument can be used over a trial frame or the patient's own glasses or it would be a perfectly simple matter to have a cell for lenses fastened to the distal end of each barrel.

The possibilities of deceiving the malingerer when one is familiar with the instrument are very great, the chief precaution being to watch carefully that he does not slyly close one eye. This is, of course, evidence of bad faith, but if the surgeon sits on the side of the worse eye and the instant it is closed puts a card over both apertures the culprit gets very little time for orientation.

ETIOLOGY OF PHLYCTENULAR OPHTHALMIA.

Capt. H. H. Turner, M. D.

PITTSBURGH, PA.

This paper urges the view that the essential lesion of the disease is a low grade chronic infection of the ethmoid, with obstruction to drainage, commonly following the acute infectious diseases of childhood. The attacks are provoked by recurring toxemias, especially of intestinal origin. This paper was presented to the Section on Ophthalmology of the American Medical Association, June, 1918.

Phlyctenular ophthalmia is second in economic importance only to ophthalmia neonatorum, and has been a veritable curse to hundreds of thousands of children. The dictum of years gone by that "the child will outgrow it" no longer suffices. True, the little victims did, in many instances, outgrow the disease, but with corneas so badly scarred that their economic usefulness was largely destroyed.

The child with classical phlyctenular ophthalmia is a pitiable sight—the more so because of the frequency with which it is encountered—constantly seeking dark corners, head hanging to avoid the direct light, lids red and swollen, eyes streaming, corneas dotted and clouded by phlyctenular nodules, swollen cervical glands, running nose and excoriated nares and lips, a child picture which, once seen, is never forgotten.

To cure a case of phlyctenular ophthalmia should mean the prevention of recurrences, not merely the relief of an immediate attack. A study of the literature impresses me with the fact that we have wandered far afield in analyzing this condition, and have lost ourselves in scientific discussion, which, altho of intense interest have accomplished little in the way of results.

The final solution of the etiology of phlyctenular ophthalmia must explain certain things: (1) why does the initial attack of ophthalmia so frequently follow the acute infectious diseases of childhood; (2) why does the process confine itself so constantly, in many cases, to only one and always the same eye; (3) why do some of the most violent cases occur among children who appear robust and healthy; (4) why does the removal of pathologic tonsils and adenoids stop the tendency in some children but not in others; (5) why does restriction of diet benefit but not cure these patients; (6) how does a dietetic indiscretion produce a lymphatic disturbance in an organ relatively remote; (7) why does the tendency disappear at adolesence?

Any theory which cannot answer these queries is not based on facts. Can perversion of carbohydrate metabolism or the tubercular theory explain these things? We all know they cannot.

It is generally conceded that the ocular manifestation is secondary. Where, then, and of what character is the primary lesion? The fact that the tendency remains limited in many cases to only one and always the same eye, over a period of years, is proof positive of a local tissue pathology, if not of the eye, then of some contiguous structure, which may be unilateral. Were a constitutional dyscrasia the principal fault, why should the local manifestation be confined to only one eye? What is the answer?

The relation of ocular disease to diseases of the accessory nasal sinuses has been a study with me for the past twelve years, and I would like to place on record a brief summary of my deductions as to the etiology of phlyctenular ophthalmia, which have no mention in the literature and which, to my mind, definitely explain all the queries made.

I am firmly convinced that the essential lesion in these cases is a low grade chronic infection of the ethmoidal labyrinth, with obstruction to drainage. Altho all patients with suppurative eth-ethmoiditis do not develop phlyctenular ophthalmia, this condition is always secondary to a suppurative ethmoiditis. The ethmoidal labyrinth is the only one of the accessory nasal sinuses present at birth, the others not being devel-

oped until several years have passed (Skillern). The outer wall of this sinus, the lamina papyracea, forms the inner third of the bony orbit, and is frequently the seat of defects in continuity, under which conditions the diseased mucosa of the sinus is brought into very intimate anatomic relationship with the orbital periosteum and the lymphatic channels of the orbit. Different theories as to the etiology of phlyctenulosis, advanced by various observers from time to time, bear an important relationship in that they are based on elements which excite or influence unfavorably the local focus of infection in the sinus. Phlyctenulosis is, in fact, a quite complicated syndrome, involving many factors, any one or more of which may be the actuating element in any individual case.

Skillern, in discussing the frequency of sinuitis in children, says that it is a very common thing for this infection to occur during the course of measles, scarlet fever, pertussis, influenza, pneumonia, etc., and that the resulting tissue devitalization favors a secondary infection of low intensity and chronic character, which may persist indefinitely. All ophthalmologists know by experience with what frequency the initial attack of phlyctenulosis follows these acute infectious diseases.

The excoriated, fissured nares, so constantly seen in these cases, while to some extent the result of the excessive lacrimation, are more largely the result of an excessively acrid discharge from the ostium of the ethmoidal labyrinth, the turgid nasal tissues, *above* the orifice of the nasolacrimal duct, being bathed in a sanious discharge, which gives a peculiar grayish appearance to the nasal mucosa and produces more or less odor. Many of these children develop early an intense atrophic rhinitis with marked ozena. Dr. Coffin, at the Manhattan Eye and Ear Hospital, made a statement about a year ago to the effect that cases of ozena in children, which he has been investigating, were to be found principally among the victims of phlyctenulosis.

The consideration of the elements producing obstruction to sinus drainage is of vital importance, as it is only by removing or correcting these elements that recurrences of the ocular manifestations are prevented.

The successful treatment of this disease requires a broad grasp of the etiologic factors and the consideration and elimination of *all* the elements which may influence unfavorably the local sinus lesion.

Obstruction may be produced by: (1) an intrasinus secretion which is too viscid or heavy to drain thru a normal, patulous ostium; (2) a mechanical obstruction in the nasal chamber proper.

1. Many of these children without intranasal obstruction to sinus drainage may be free for several years from any tendency to phlyctenular ophthalmia. Later, owing to a degeneration of the intrasinus mucosa, the secretion may become too thick to drain properly, and we then have the essential element—that of obstruction to drainage —with the subsequent development of eye symptoms.

2. The several elements which may produce mechanical obstruction from within the nasal chamber proper are (a) pathologic tonsils and adenoids; (b) deflected septum, spurs, or tight nostrils; (c) many forms of general toxemia, of which the most frequent is intestinal in origin.

A. Hypertrophied tonsils and adenoids produce a stasis in the lymphatic flow, with intumescence and bogginess of the intranasal and intrasinus tissues and obstruction to sinus drainage. The retained, infected sinus contents accumulate under pressure and are forced into lymphatic channels, being carried along lymphatic pathways to the tissues of the conjunctiva or cornea, where they lodge and produce the typical phlyctenular lesions. The removal of such diseased tonsils and adenoids will effect a relief of the condition only when they are the sole exciting factor.

B. As is well known, the separation of the superior maxillae is produced largely by the wedging action of the upper teeth. When these are badly decayed or erupt abnormally, this wedg-

ing action is lost and we find a dental arch flattened laterally, with the incisors projecting to varying degrees, a contracted, highly arched palate, and narrowed nasal chambers, with deflected or spurred septum, produced by the vertical encroachment of the highly arched palate and the consequent buckling of the septum. These cases, almost without exception, have obstruction to sinus drainage on one or both sides, and, if a chronic infection be present, are very likely to develop a typical phlyctenular ophthalmia.

I have in many instances secured excellent results by referring these patients to a skillful orthodontist, who, by spreading the superior dental arch, has so widened the nasal chambers as to relieve obstruction to sinus drainage, and caused the phlyctenular tendency to disappear.

As the child with a phlyctenular history approaches the age of adolescence, the facial and cranial bone spaces develop, the nasal cavities widen, and the impediment to sinus drainage becomes less marked and possibly entirely disappears. Therefore the tendency usually subsides, in the vast majority of cases, at about this age, and remains quiescent, except at such times as the drainage may become blocked by an acute intumescence of the local soft parts.

C. Given hyperplasia of the middle turbinates or accessory sinus tissues (which is constant in these cases), many forms of constitutional toxemia will produce marked circulatory disturbances in the nasal and orbital tissues of the same side, the opposite side remaining normal, if the nasal condition be unilateral. The circulatory disturbance in the nostril proper will manifest itself by an intense intumescence of the local parts, with partial or complete blocking of the breathing space, often with considerable pain and sense of pressure.

The toxemia, in my experience, most frequently found originates in the intestinal tract. Hajek states that indiscretion of diet will produce an acute exacerbatin of a chronic sinuitis.

There is a peculiar reflex perversion of the intestinal digestive function, which is constantly found in the entire group of sinus disease, including phlyctenulosis, and which, observation leads me to believe, is produced by way of the sympathetic system. The relation is vicious, in that the autointoxication produced by absorption from the intestinal tract intensifies the pathologic process which produces the reflex. This digestive perversion is simply an instance of the functional disturbance of the digestive act which we now know may be produced by any persistent irritation of the sympathetic system. I have seen many of these cases in which the chronic digestive trouble disappeared entirely or was vastly improved following the correction of a sinus pathology.

The intestinal condition is characterized by acidity, with fermentation, flatus, eructations, etc., the intensity of the functional disturbance varying in different individuals, according to the intensity of the focal irritation to the sympathetic system and the susceptibility of the patient.

Unfortunately, radical procedures for the securing of free sinus drainage—such as curettement of the ethmoid, resection of the septum, or partial turbinectomy—are not usually applicable in childhood. Therefore it is doubly essential that all factors which may influence unfavorably the local lesion be considered, and eliminated so far as may be possible.

Whether the local tissue reaction in the nasal structures, secondary to intoxication of intestinal origin, be an example of anaphylaxis or not is a matter of purely academic interest in this relationship. The essential point is that the focal reaction, with obstruction to sinus drainage, may be relieved with certainty in these cases by a proper regulation of the diet.

The object in outlining a diet should be to exclude those elements which already contain such acids as would add fuel to the fire, and those which, because of indigestibility, would add to the existing status the acids and toxins formed during the process of intestinal

fermentation and putrefaction. My experience has led me to exclude, as a routine, all raw fruits excepting only the citrus group, aside from which Metchnikoff was certainly correct, as regards this group of cases at least, when he stated that raw fruits are harmful, but that cooking renders them innocuous. I do not believe that a carbohydrate free diet is either indicated or desirable in these cases, but do believe that the more indigestible carbohydrates, such as oatmeal, sweet potatoes, and navy beans, should be absolutely excluded and moderation be advised in the consumption of even the lighter starches. We must remember that the diet, to produce the desired result, must be constantly followed, which would be absolutely impossible under many of the projected regimens, as the child's general nutrition would suffer sadly within a short period. Regarding confections, I allow a moderate amount of plain candies—fondants or plain hard candies—occasionally, with meals, but exclude chocolate in all forms.

The ophthalmologist in handling these cases must, perforce, be somewhat of an internist, and study his patient from all angles, would he accomplish results.

In view of the fact that the flow of the lymphatic current from the head is downward, an involvement of the lymphatic glands of the neck is to be expected when there is a focus of infection above. Also, since the inspired air, with its myriad forms of bacterial life, passes constantly over this devitalized focus in the nasal passages, a mixed infection—in some cases tubercular—is certain to occur, and in these cases the various organisms may or may not be identified in the broken-down glands of the neck.

The general medicinal measures for the relief of this condition, which have been employed empirically for many years—the iodids, sodium salicylat, cod liver oil, etc.—have all very definite indications when this relationship is grasped.

In the early acute stages, the internal administration of atropin or belladonna in small doses for a few days is often of great benefit, and has been widely employed for years by rhinologists for the purpose of drying up nasal secretion and diminishing pressure. To my mind, in the treatment of phlyctenulosis, this procedure parallels too closely the use of opiates in intestinal conditions, which was largely discarded years ago because, by locking up deleterious elements, it eventually did more harm than good.

The shrinking of the nasal tissues about the ethmoidal ostium, to afford free drainage, and the liberal, daily application of a 2 per cent solution of silver nitrate to the middle turbinate and neighboring nasal tissues, by means of a dropper, is to me a far more logical procedure, as it disinfects the local tissues so far as is possible, depletes the local circulation, and produces a free outpouring of the sinus contents.

The internal administration of the iodids, *in small doses*, further promotes free sinus drainage by causing the secretion to become more fluid, and at the same time tones up the depraved mucous membranes. Large doses of the iodids in these cases are frequently injurious, as the intumescence of the nasal tissues, often seen when large doses are employed, blocks sinus drainage and so defeats the very purpose for which the drug is employed.

SUMMARY.

Taking the queries made, in the order given:

1. The primary attack of phlyctenulosis follows the acute infections of childhood so frequently because an infection of the ethmoidal labyrinth has occurred during the disease, and a secondary infection has taken place owing to the diminished resistance of the intrasinus tissues.

2. The process is constantly unilaeral in some cases, because only one ethmoid has been infected—that on the same side as the affected eye.

3. Some of these patients appear robust and healthy, because the secondarily infecting organisms are less virulent and the constitution of the

child more resistant to the toxins absorbed from the local focus.

4. In cases that remain clear after a tonsillectomy and adenoidectomy, the tonsils and adenoids, by producing an intumescence of the soft parts above, have been the principal factors creating obstruction to sinus drainage.

5 and 6. Given hyperplasia of the middle turbinate and intrasinus tissues, which is constant in these cases, many constitutional toxemias will produce an intense local intumescence with obstruction to sinus drainage. The toxemia most frequently associated originates by absorption from the intestinal tract, and may be controlled by a proper regulation of the diet. This eliminates one element which may produce obstruction to sinus drainage, but cannot *cure* the phlyctenular tendency because the toxemia is only a contributing element.

7. The tendency usually disappears at adolescence, so far as eye symptoms are concerned, because the development and widening of the nasal chambers has relieved the obstruction to sinus drainage.

CONCLUSION.

I wish to state that by following the procedure outlined herewith, we have practically eradicated the recurrence of these attacks in an orphanage caring for 1,300 children, to which I have been ophthalmologist for several years, the cases presenting usually being new, and especially following an epidemic in the institution of one of the acute infectious diseases.

I am aware that this course of reasoning may be considered heretical by some, but if the members of the section will study these cases along the lines I have indicated, in conjunction with a competent rhinologist, they will find that the same conclusions must inevitably be reached.

PERSPECTIVE FOR AVIATORS.

WILLIAM H. DUDLEY, M. D., F. A. C. S.

LOS ANGELES, CALIFORNIA.

This paper discusses the peculiar conditions under which aviators are compelled to judge of distance, and raises the question whether the tests that have been relied on to determine fitness for the aviation service are sufficient.

Perspective in its origin means to see thru, and in its usual application this term answers the purpose well enough, i. e., when applied to terrestrial objects; but when applied to objects floating in the air above the horizon, the conditions are so radically different, that it largely loses its significance. Hence, in contrast with terrestrial, I shall refer to aerial perspective; altho this term is often used with quite a different significance.

In an article appearing in this journal in the April number (1918), by Isadore Franklin (p. 236), discussing the general subject of perspective and stereoscopic vision, the author enumerates the various faculties brought into play in the ability to judge relative as well as positive distances, as: the interpupillary distance, the sense of the play of the muscles, which he states can be of value only within a short distance, the play of the muscles of accommodation which he considers of the next importance; next he considers the blurring of objects out of focus, i. e., objects proximal to, as well as those beyond the point of fixation; but here again the effect is confined to a relatively short distance. Next he states that the apparent size of objects is of great value, and it is my opinion also, that in what might be called terrestrial perspective, these various functions, etc., are of great importance in judging relative as well as positive distances.

For the purpose of testing aerial perspective in candidates for the air service in the U. S. army, the war depart

ment of this country has adopted a method which I understand had been in use by the German government for this purpose for some time previous to the breaking out of the present hostilities; and upon the use of this instrument must depend all of our reasoning relating to the subject in hand. This instrument is simply an ordinary stereoscope provided with a card upon which has been photographed various objects in silhouette so arranged as to give the examinee, with proper aerial perspective the impression of decidedly varying distances from the observer of the objects on the card.

This effect is produced by placing the identical pictures on the two sides of the card at slightly varying distances from each other; those appearing in the foreground having a slightly shorter distance between them than those appearing farther away. This variation in the distance between the pictures on the two sides of the card may be exceedingly small, however, for it is stated that so small a variation as 1/100 of a millimeter is sufficient to give perspective effect to one with aerial perspective.

On the card in use by the examiner of candidates for the air service, however, the variation between one set of pictures, and the set nearest is not less than 1/15 to 1/10 millimeter, and this produces an effect which is quite decided. The card furnished the examiners contains ten sets representing objects familiar to the Teutonic eye, such as castles, forts, lighthouses, cathedrals, battleships, etc., and over each object is placed a small number for identification. Much ingenuity has been used in the setting in order to deceive one who should depend upon anything but his perspective sense. For example, the largest picture on the card, a sailing vessel with all sails set, and placed at the bottom of the card, consequently in the foreground, is really the farthest in the setting, while the one next nearer is a small warship.

When taking up the work of examining candidates for the air service something over a year ago, the writer at once became much interested in this particular part of the work, and with the hope of satisfying himself as to just which of the special elements of vision, etc., were the determining factors in aerial perspective, private notes were kept in several hundred cases as to (1) the pupil distances; (2) muscle balance; (3) power of convergence and divergence; (4) the accommodation, and (5) the acuity of vision. These, together with numerous cases with abnormalities of these conditions, have been made in the private office; and it may be stated here that the results of these studies have been to upset nearly all of his preconceived notions.

In reference to the pupil distance, it seemed at first that this must be influential in this perspective. Sometime in December, '17, someone in official position appeared to be thinking along similar lines, for we received notice to record this finding—which question was not included in the questions on the examination chart—tho the writer long before this had become satisfied that it had no influence in this kind of perspective, as quite often one with very narrow p. d. would call off the number on the stereoscopic card rapidly and correctly without error, while another with a wide p. d. and with other facilities well developed would make a bad mess of it.

It did seem, however, that accommodation must play an important part in this faculty, till we took occasion to try the test on those under complete cycloplegia when we found that they used the stereoscope fully as well as they did with the accommodation intact. Of the question of vision, it may be stated, so long as it was sufficient to make out details it has not appeared to effect the ability for proper perspective. The varying size of objects seen against the sky is very deceiving to one whose perspective is not good, and in the use of the stereoscope, as previously remarked, the candidate will be almost sure to place the large sailing vessel well in the foreground, while the candidate with this faculty well developed will seldom make a mistake.

The question of the play of the muscles of convergence, however, is not so easily disposed of. Somewhat early in my experience in these examinations, it seemed to me that at least the possession of convergence with somewhere near the standard relation of abduction to adduction, usually reckoned as one to three, must be necessary to be able to qualify in the examination in this test.

Our regulations provided that in case the muscle balance test shows exophoria or esophoria of more than two prism diopters, the relation of the convergence to divergence must equal three to one, in order to qualify. However, after going over several hundreds of these records, it seems that my conclusions will hardly stand.

In giving the details of some of these cases in regard to the muscle relationship which were selected out of many, the numbers must be understood to represent prism diopters of convergence and divergence, abbreviated to ad. and ab. It seems hardly necessary to give the ages of the individuals, as they were mostly between eighteen and thirty, and a careful review does not show that these conditions are especially influenced by age. Among those whose amount of positive and relative convergence was at least fair, and who in spite of this showed quite imperfect perspective, the following have been selected. I will state that these muscle examinations were all carefully made with Reimold's optometer, equipped with the rotary prism, which was used in the examinations.

No. 269: Orthophoric, ab. 8, ad. 19, great difficulty with the stereoscope, disqualified.

No. 552: Orthophoric, ab. 4, ad. 14, no perspective.

No. 785: Orthophoric, ab. 8, ad. 15, perspective bad, disqualified.

No. 173: Orthophoric, ab. 11, ad. 20, disqualified.

No. 126: Orthophoric, ab. 3, ad. 13, disqualified.

No. 548: Orthophoric, ab. 4, ad. 15, disqualified.

No. 179: Orthophoric, ab. 8, ad. 14, disqualified. This record simply shows that these cases were apparently well supplied with sense of muscle play, tho it was not sufficient for proper aerial perspective; on the other hand, a series of cases with especially bad convergence, both positive and relative, proved well qualified with aerial perspective in the test. For example, No. 484: Orthophoric, had ab. 6, ad. 3, perspective satisfactory. No. 589: Orthophoric, ab. 6, ad. 6, perspective correct. No. 77: Orthophoric, ab. 6, ad. 4, qualified. No. 128: Orthophoric, ab. 8, ad. 8, qualified. No. 274: Orthophoric, ab. 10, ad. 4. (This man, tho qualifying in the perspective test, was disqualified by his 5° of exophoria.) No. 688: Orthophoric, ab. 11, ad. 9, qualified. No. 772: Orthophoric, ab. 12, ad. 8, qualified. No. 193: Orthophoric, ab. 12, ad. 10, qualified.

This shows that so far as our experience goes, in the examination of a large number of prospective aviators, supplemented by a good number of similar cases in the private office, none of the faculties possessed by our eyes and their adnexa appear, singly or collectively to be sufficient in certain cases to provide us with perspective, when we do not have terrestrial conditions to help us. On the other hand, quite a series of cases which appear particularly disqualifying, are able to present a perfect aerial perspective.

Taking into account these considerations, the question arises, upon what then must we depend for our ability to look into space and determine, aside from size, of two or more objects, which is nearer or farther from us. In Dr. Franklin's article, previously referred to, he makes the statement which appears to come very near my own conclusion when he states—"the sense of depth and solidity are neither essentially ocular, nor tactile, nor muscular in their nature; but are a psychic complex, outgrowing principally from three (previously mentioned), senses, but embracing other mental reactions to bodily experience. Or to put it another, briefer way: for our ability to determine perspective in space, the fac-

ulty now under consideration, there must be present some special cerebral center, probably closely associated with centers controlling muscle balance, and possibly some of our other ocular faculties, with which by the aid of binocular single vision we are able to exhibit this particular function.

Now a word in regard to the practical application of these muscle tests. The question has come to mind as to whether the simple examination for exophoria and esophoria in the lateral balance in all cases is sufficient. This precise method having been adopted by those in charge of the examination for the air service presupposes that it is; and yet it seems quite possible that with practically orthophoric conditions as found with the phorometer, it frequently occurs that the convergence is low, and in fact it may have its relation to divergence reversed as occurred in some of the cases reported, and yet be given a passing mark.

The danger of this condition—weak convergence—under the trying conditions in which the eyes of the pilot are placed, Col. W. H. Wilmer has recently stated (Arch. of Ophthalmol. v. 47, p. 447). "After the strain of service the tendency of the weak muscle becomes a manifest error, a weak convergence becomes a dynamic divergent squint." From the fact that so many students in the air service die from accident—in many cases it seems an utter impossibility to determine the cause—it appears entirely possible that something of this nature may have occurred, that due to the heavy strain he is suddenly confronted with a double vision, which so confuses him, that he loses control of himself and likewise of the machine, and one more is added to the fatalities of the aviation field.

OPHTHALMOSCOPY WITH RED-FREE LIGHT OF VOGT.

Demonstration of Method with Normal Fundus

ROBERT VON DER HEYDT, M. D.

CHICAGO, ILLINOIS.

This is a description of the effects of red-free light upon the ophthalmoscopic image and the method of obtaining such light which was presented to the Chicago Ophthalmological Society, November 18th, 1918.

Vogt, now of the University of Basle, published in 1913 his first reports on ophthalmoscopy with the red-free source of illumination. Since then he has done a great deal of research work in the application of this new method, and reported much of interest pertaining to the normal fundus. To this have been added of late some very important diagnostic observations in pathologic fundi.

Our usual illumination for the fundus, the old petroleum lamp—the Welsbach—as well as the electric bulbs, give a more or less yellowish white light dependent on the temperature to which the respective carbons are heated. A nerve head seen with a white light will seem more pale and even "atrophic" when compared to one seen with a light more rich in yellow. Therefore the term white is a relative one and in a measure a matter of contrast. The yellow of the macula cannot be seen intravitally with ordinary illumination on account of too little contrast and too much yellow in the light. The rich in red reflection returning from the sclera and choroid also aid in reducing its visibility.

This yellow coloration of the macula, a much disputed point especially studied and investigated by Dimmer and Gullstrand, is now certain, and can be seen in the living eye by the light filtration of Vogt. He says if we are

able to remove the red rays from the ophthalmoscopic illumination and if the fundus is not excessively pigmented so that it will reflect a fair quantity of light entering, we can make observations by contrast not otherwise possible.

This illumination will therefore be green and in addition its yellow and blue rays may modify it to bluish-green. It is also necessary to reduce the ultraviolet, violet and indigo rays.

The elimination of the red rays from our light could be accomplished by prismatic dispersion, separation and a reuniting of the necessary components. This is technically a complex problem, the loss by elimination, reflection and absorption would too greatly reduce the quantity of light. A method by filtration is probably the most simple; however, the red of the spectrum is the most difficult to eliminate.

Our most common filters are colored lenses made by combinations of white glass with inorganic metals. Also watery solutions of these metals as well as anilin dyes in water, alcohol or gelatin may be used. Great difficulty is experienced in completely removing all traces of red. All combinations of copper acetat solutions on the one hand and anilin dyes such as Malachite green, acid green, brilliant green, etc., have been tried without success.

The blue glass of Schott and Co. is the only known glass to eliminate all red in the thickness of 5 mm. It, however, allows the violet and indigo to pass, which latter are contraindicated for our purpose, besides eliminating probably all of the so necessary yellow.

As filters, Vogt used two solutions contained in 10 c. m. square glass vessels with parallel sides and of about 1 c. m. lumen.

Solution No. 1—Aqueous solution of copper sulphat, 30 per cent.

Solution No. 2—Aqueous solution of erioviridin "B," an analin dye in shade somewhat darker than solution No. 1.

For illumination in arc flame of the projection type fed by a direct current of 40 amperes. Affolter of late finds a Leitz arc lamp with condensing lens sufficient. This is mounted in an asbestos lined box.

NORMAL FUNDUS.

With the red-free illumination many retinal reflexas at first quite confusing are seen. These are due to the absence of the long wave spectral components in the yellow blue light.

When examining with a purely red light by contrast a scarcity or almost total absence of these reflexes is found. Some of the surface reflexes are flat and wander with the motion of the mirror, probably a drawing tense of the retina in certain areas. These are not found in the macular zone. Radial from this zone we often find superficial small linear reflexes, probably folds.

The vessel surface reflexes are similar to the ones seen with ordinary light, except a delicate moss-like area between zones otherwise sharply demarcated is shown with the red-free light.

The yellow discoloration of the lens in age can be measured with this light and the contrast of fundi in monolateral aphakia is quite marked. The retinal nerve fibres are faintly visible with ordinary illumination, especially near the papilla in youthful individuals. With the red-free light, however, they are plainly visible all over the fundus and their course can be followed easily. It is most interesting to trace them towards the macula. The central fibres are directly horizontal. Above and below these are bundles that surround the foveal zone in a close sweeping arc at its temporal border. These are bound by circular enveloping fibre bundles that meet and cross basket-weave-like in a zone temporal of the macula. At first they meet at an obtuse angle which becomes acute and more acute as we recede from the macular zone.

The larger blood vessels are above this layer while numerous smaller vessels can be seen intermingling and at times covered by these nerve fibre bundles.

Fundus vessels seen with the red-free light are black on a light background due to the absence of the diffuse red of the choroid. Of particular interest are some of the findings in the macular region. Here very minute vessels may be followed over the edge of the macula into its depression until they are lost in the foveal reflex. A well-defined, small granulation of the macular surface is seen. Small macular hemorhages are easily discernible and larger hemorrhagic and exudative zones in choroiditis quite easily located even through a diffusely clouded vitreous.

The foveal reflex ordinarily found only in youthful individuals can often be observed with the red-free light in old age.

The macular zone is of a radiant yellow color and its diameter about one-third that of the disc. It is therefore easily visible and can be located in pathologic fundi in cases where this would be impossible with ordinary light.

It has been conceded and especially emphasized by Haab that the darker red of the macula is due to increased pigmentation. With the red-free light all pigment appears black. There is, however, no black mottling in the macular zone, consequently no pigment. As the macula is now definitely known and seen to be yellow, its darker red contrast found with ordinary illumination can only be ascribed to an intensification by the yellow coloration. This can be easily shown by placing a yellow lens over part of a red zone the color of the fundus. The red under the yellow lens will be of a more intense red.

We have therefore with the red-free light the first absolute demonstration of the yellow coloring at the macula in the living eye. A new explanation of why this zone is more intensely red with ordinary illumination. The ability to measure this zone more accurately, comparing it with the usually larger size of yellow discoloration found after death.

We can note new details of the macula as respects its size, reflexes and surface, absence of pigmentation (except secondary to disease), vascularization and the direction of vessels. We can also with it measure and by comparison in various eyes study the yellow discoloration of the lens in age.

Most important is the ability to follow minutely the direction of the nerve bundle and fibre layers in the retina—a matter of great importance; as I will endeavor to show in the near future by presenting some new and intensely interesting findings by Vogt in pathologic fundi as shown with the red-free light.

CORRECTION OF CROSS-EYE DEFORMITY.

J. A. Kearney, M. D.

NEW YORK.

This is a review of the author's practice and teaching in the New York Polyclinic Medical School and Hospital, based upon 175 consecutive operative cases.

The chief concern of cross-eyed patients is the correction of the deformity. Cross-eye (Strabismus Squint) cases as a rule are seen in consultation by the eye surgeon at certain ages and under certain conditions and it is always interesting to note the compelling cause of the first visit.

The child in arms is seen by us when a worried mother notices the infant's eyes are crossed, next period when as a sensitive youth he suffers deeply the gibes of his school companions, somewhat later on when he is chagrined to find that because of this deformity he is unable to secure a position for which

he has trained and is perfectly capable of filling, still later on in life when he discovers that the operation for the correction of squint is not a serious one and that it is possible to obtain a good result at any time from nine years of age onward. Certain other compelling conditions are familiar, the young girl who is not invited to parties given by her friends on account of her appearance, the young person during courtship for obvious reasons, and the cross-eyed who are avoided by superstitious people. No other case is more gratifying than when a client applies for the correction of a squint deformity referred by a patient upon whom you have operated.

Strabismus is paralytic (partial, complete), or concomitant (monocular, alternate). In complete paralytic squint the eye is in malposition and can not be voluntarily moved in the direction of the paralyzed muscle; in partial paralytic squint the eye in faulty position can voluntarily be rotated in the direction of the paralyzed muscle, but not to the normal extent.

In concomitant squint the eyes rotate equally, the affected one maintaining the same angle of deviation in all positions. Each eye fixes alternately in alternate concomitant strabismus; and in monocular concomitant strabismus one eye fixes and the other constantly deviates. Vertical concomitant strabismus is uncommon and we have to do chiefly with lateral deviations, convergent and divergent concomitant strabismus.

An infant with a noticeable squint requires a careful direct method ophthalmoscopic examination of the fundus of each eye. They are neurologic cases when we discover as we frequently do edematous changes in the fundi, that indicate an increase in the intracranial pressure. Measurement of the degree of intracranial pressure should be made and recorded at once, by a spinal mercurial manometer at lumbar puncture to verify the fundus findings; and if it records a decided increase above the normal, the excess of pressure is usually due to an intracranial hemorrhage at birth. There is generally a history given of difficult or instrumental delivery of the child and subsequent occasional convulsions. Spasticity and other neurologic disorders are the usual sequellae of birth hemorrhages, unless the clot is removed and intracranial pressure relieved by a decompression operation. If this procedure is deemed necessary the earlier it is done the better. Often we find in the fundi of cross-eyed infants optic discs that are decidedly pale thruout (atrophic), as the result of faulty development in embryo and sometimes associated with stigmata (high palatal arches, cleft palates etc.) elsewhere from the same cause. These are neurologic cases also.

Mentally normal children with strabismus, in which no changes are noted in the eye grounds, with or without errors of refraction existing, or in which recent exudative changes are observed become the subsequent charge of the ophthalmologist.

Since no one cause has been ascribed for strabismus, the usual attending abnormal factors may be looked for and corrected if possible, the earlier the better. Errors of refraction, amblyopia and faulty fusion are the usual concomitants.

If an error of refraction is present suitable lenses worn constantly give the best results in correcting a squint deformity at a period when a child's eyes are observed to be crossed at times and straight at others, no matter what angle of deviation obtains; or when the angle remains constant and is less than 15 degrees. Glasses may be worn by children as young as one and one-half years of age, and it is never too early to prescribe a correction for an existing error of refraction in a developing strabismus. Correcting lenses, however, seldom have any effect upon a squint deformity of 15 degrees and over, if the eye that turns remains in malposition for three months or longer.

The correction of faulty fusion is rarely successful because of the immaturity of the patient at the time the treatment would avail; and even under the best conditions excessive dili-

gence is required to get a small percentage of good results. An occasional good result is obtained in amblyopics when the affected eye is compelled to fix by placing a correcting lens before it, and shutting off fixation of the good eye by a shade, or atropinizing it.

Conservative methods have been tried out usually, on all strabismic patients who are particular about their looks, before the operative age (9 years) is reached; and when an eye surgeon is consulted a review is made of the history and treatments that had been given, and if stated nonoperative methods have failed to correct the deformity then surgical measures are advised.

Operations upon the external ocular muscles for the correction of squint are advisable when the patient is 9 years of age and over, and all necessary nonoperative measures have been tried and have failed to correct the deformity. The choice of procedure depends upon the character and angle of strabismus that exists, and the nature and extent of lateral rotations. Under usual conditions the deformity in all concomitant strabismic eyes may be corrected to parallelism by definite surgical procedures.

If the external lateral rotation of the squinting eye is found to be normal, in monocular concomitant convergent strabismus that measures 15 degrees of deviation, a complete tentotomy of the internal rectus of the affected eye usually corrects. If the deviation measures 30 degrees a complete tenotomy of the itnernus followed by an advancement of the externus of the squinting eye usually corrects. If the deviation measures 45 degrees complete tenotomies of the interni of both eyes usually correct.

However, if it is determined that the external lateral rotation of the squinting eye is not sufficient, but the amount of deficiency is made up by excess of internal rotation, or in other words the lateral excursions are equal, but the plane of rotation is advanced to the nasal side, then an advancement of the external rectus is done first and usually corrects a deviation of 15 degrees when it exists. If the deviation measures 30 degrees an advancement of the externus is done first and when the reaction subsides the internus of the same eye is completely tenotomized and usually corrects. If the deviation is 45 degrees an advancement of the externus of the squinting eye is done first followed by a complete tenotomy of the internus of the same eye when the reaction of the advancement operation subsides, and later on an advancement of the externus of the good eye usually corrects.

When tenotomies are indicated in concomitant convergent strabismus a complete tenotomy of the internus corrects 15 degrees and if less than 15 degrees are to be corrected, partial tenotomies are done. When advancements are indicated in concomitant convergent strabismus 15 degrees are corrected by the usual placement of stitches in the externus, but a little more or less can be accomplished by entering the stitches on either side of the usual position.

In alternate convergent concomitant strabismus advancements of the external recti of both eyes are done and the amount to be corrected is divided between both eyes. If the advancements do not correct the entire amount of squint, for the deviation remaining, partial tenotomies of the interni of both eyes are done and should be equally divided between them.

In the divergent type of concomitant strabismus, tenotomies of the external recti have very little effect upon the cosmetic result but the advancement of the internus may be regulated to correct up to 45 degrees of deviation This is a most satisfactory procedure on account of the good size of the internus muscle, and experience guides one in the placement of stitches to correct various amounts of deviation.

Operations for the correction of paralytic squints are unsatisfactory as a rule, but it is possible at times to pull and fix an eye in straight position.

The usual complete tenotomy in which the aponeuroses of the muscle as well as the tendon are severed, and the advancement operation, a modifi-

cation of Landolt's, give the best results in the writer's hands. In the last 175 consecutive operations for the correction of squint deformity, parallelism has been obtained in all of them. There were 155 monocular convergent concomitant, 16 divergent concomitant, 3 alternate convergent concomitant and one convergent paralytic (complete).

HYPERPLASTIC EXUDATIVE RETINITIS (NONHEMORRHAGIC).

J. W. Jervey, M. D.

GREENVILLE, SOUTH CAROLINA.

The report of four cases and statement of reasons for grouping them as illustrating this form of retinitis. A thesis submitted, and accepted, as a candidate for membership in the American Ophthalmological Society, 1918.

True hyperplastic, exudative, nonhemorrhagic phenomena in and apparently adjacent to the retina are rare. The appearances which they present to ophthalmoscopic examination are frequently similar to, and perhaps often indistinguishable from, the lesions resulting from previous hemorrhagic extravasations. In fact, the ultimate result, subjectively and objectively, of organized hemorrhagic and nonhemorrhagic exudates might conceivably be pathologically identical, as in the lesions of retinitis proliferans, which may have their origin in either form of exudation.

This latter form of retinitis is of course described in all modern text books, but the rarity of its occurrence may be realized by the statement of Weeks that he had seen but two cases in twenty-four thousand private patients, and of Schöbl, quoted by Weeks, who observed five cases out of 179,057 patients. The common acceptance of its etiology is hemorrhagic extravasation from the retina into the vitreous. It has been pointed out, however, that it may occur consequently upon the ejection of a fibrinous exudate or coagulum, with or without the presence of blood corpuscles (Weeks).

Leaving out of consideration, for the present, cases of retinitis circinata, which will be referred to later, the writer has observed at least four cases showing lesions in six eyes, of what appeared to be true organized retinal exudates, nonhemorrhagic, three of them being confined within, or adjacent to the retinal layers, and one combining this type with the currently described type of retinitis proliferans extending into the vitreous body. In none of these cases was there any evidence of previous or present hemorrhage at the site of the lesions, and in all except one the development of the processes was watched from week to week and month to month under ophthalmoscopic observation.

In view of these observations, which are detailed below, the writer suggests that proliferating or granulating or chronic inflammatory (neoplastic) tissue may occur within as well as without (with an origin within) the retinal layers; that it may occur without preceding hemorrhagic phenomena; and that whether within or without the retinal layers these lesions may properly be classified as hyperplastic exudative (nonhemorrhagic) retinitis.

From all that is known of retinitis circinata, it would seem justifiable to include this type in the above classification, the difference in the ophthalmoscopic picture being due merely to the different arrangement of the lesions.

The identification of hyperplastic exudative retinitis with the conditions described by Coats in 1909 as a "disease of the retina, hitherto insufficiently differentiated, which is charac-

terized by the presence in the fundus of large masses of white or yellow exudation; usually there are also groups of cholesterin crystals and hemorrhage" (Massive Exudation of the Retina, (Coats), seems more than possible. There seem to be, however, some interesting points of difference. For instance, Coats states that "in the only case of this disease which has so far been examined in a recent stage, the white mass in the fundus was found to be due to a disintegrating hemorrhage." In three of the subjoined cases the growth and development, and in one case the retrogression of the lesions, were observed by the writer over a considerable period of time, and at no time could hemorrhage be suspected of having a part in the origin or progress of the lesions.

Coats remarks that "in an allied form of the disease, or in a variety of the same form, strange types of vascular disease are found — fusiform and globular expansions, kinks, loops, glomeruli, etc.,—as well as the more common types, such as constriction, white ensheathing, etc." Interestingly enough, this "allied form" occurred in the left eye of Case I, described below, the right eye having been enucleated after destructive blindness had ensued on a continued development of the hyperplasia and excessive glaucomatous tension.

In at least two of these cases, II and IV, a neogenetic vascularity was observed as a part of the hyperplastic processes. This vascularity has an apparent tendency to disappear from ophthalmoscopic view after a longer or shorter lapse of time, but whether from actual resorption or from becoming obscured by cellular infiltration of leucocytes or the development of fatty degeneration, it seems difficult to determine, tho the writer inclines to the two latter hypotheses. The evidence leading to this conclusion was quite marked in the case of the enucleated right eye of Case I. Here the chief lesion was about the entrance of the optic nerve. In enucleation the nerve was severed three or four millimeters behind the bulb; and surrounding the nerve, beneath the sheath, and giving it a somewhat lobulated appearance more than twice its normal size was a mass of what looked macroscopically like chronic inflammatory, or granulation tissue with finely spun vascular elements—certainly well organized hyperplastic tissue, and certainly a part of the process ophthalmoscopically observed; and from indications at the time, proved by subsequent events, evidently not malignant. There is no doubt that this process extended further up the nerve than the point of severance. In Case II a well marked, fine vascularity appeared in the exudative mass, subsequently disappearing from ophthalmoscopic view.

In none of the writer's cases were there any of the stigmata of lues, inherited or acquired, and repeated examinations clinically and by laboratory methods of cases I, II, and IV, failed to show positive signs of either syphilis or tuberculosis. In none was there a history of trauma obtainable, except as noted in report of Case II, below. It is true that in Case I, while the second eye was giving us some concern, Dr. G. E. de Schweinitz, who was the consultant in the case, reported that there was a strong positive reaction to the von Pirquet test. However, this was subsequent to repeated subcutaneous and von Pirquet tests previously made (with negative results) under the writer's direction, and the possibility of anaphylaxis may be properly considered. Dr. de Schweinitz quotes the clinician's report as follows: "Altho the physical signs at the right apex are not sufficient in themselves to make a diagnosis of tuberculosis, and an X-ray examination is always a little uncertain, when these are taken together there seems little doubt that a lesion in the upper lobe exists, and the probability is that the lesion is a tuberculous one." Fifteen months have elapsed since this report was made and no further evidence of tuberculosis has been obtainable.

In all the cases except III (who was seen only twice), all possible points of focal infection were satisfactorily eliminated from consideration as etiologic

factors except as follows: Case I had suspicious faucial tonsils, which were enucleated; and later X-ray examination of the various sinuses gave apparently positive evidence of an old right mastoid infection. This mastoid was opened and cleaned out, but there proved little evidence of diseased processes present. In Case IV it was discovered that active pus tonsils were present, and these were promptly enucleated. The effect of the removal of these foci in Case I is rather difficult of estimation, but on the whole it may be said that the result appears satisfactory. At any rate the remaining eye is in a more quiescent condition since this interference and vision is normal with correction. In Case IV a sufficient time has not yet elapsed since the removal of the tonsils to warrant a statement of intraocular effects, tho the patient expresses herself as feeling much better generally.

In these cases the circulatory, intestinal, and kidney functions were repeatedly, and the writer believes, carefully and thoroly investigated with results negative in informative value. Cases I and II showed undoubted benefit from massive doses of iodid of potash, but this can hardly be taken as indicative of anything definite as to the etiology.

After observing for several months the development of the process in Case I, right eye, the writer had made a diagnosis of probable malignant tumor. Dr. de Schweinitz, however, after a careful study of the case, suggested "massive exudation of the retina—Coats," or else the rarer type described by von Hippel under the name of "angiomatosis retinae," but concurred in the advice to enucleate the eye, "inasmuch as in either circumstance the eye is sure to go on to secondary glaucoma and complete blindness, and as a staphyloma is already beginning to form in this eye." The writer is now convinced that de Schweinitz's diagnosis of massive exudation was practically correct.

With these cases as suggested above, it would seem proper to classify, clinically, those conditions of exudative, nonhemorrhagic retinitis which are typified by the so-called retinitis circinata, retinitis proliferans of nonhemorrhagic origin, and the hyperplastic retinitis of syphilitic and traumatic origin which are not of hemorrhagic formation. The cases of the type which the writer is reporting (like retinitis circinata and retinitis proliferans of nonhemorrhagic origin) must be regarded for the present, as idiopathic—much as we may dislike the term; tho we must necessarily accept the dictum that may be tersely put in this form: In the presence of exudate there must be a departure from the vascular normal. This, for the present, is as far as we can get etiologically.

The suggested classification would come entirely within the purview of Fuchs' statement (Textbook of Ophthalmology—translated by Duane, Fifth Edition, p. 589) of the anatomic changes in retinal inflammation, and would serve to clarify and make more readily understood the diagnosis of certain rarely observed and hitherto seldom recognized conditions whose ophthalmoscopic changes and pathology have been veiled in more or less obscurity.

(It is a matter of deep regret to the writer that, owing to a mistake on the part of his pharmacist in furnishing too strong a solution of formaldehyd, the eyeball enucleated in Case I was rendered unfit for laboratory examination, tho Dr. de Schweinitz and his pathologist made every effort to use it.)

ABSTRACT OF CASES.

Case I. June 10th, 1912. C. S. C. White, male, age 15 years. School boy. Excellent family and environment. Right eye went suddenly blind (in space of two or three days), two months before this date. Constant severe parietal headaches right side. Health otherwise good. Nothing of interest in previous personal or family history, except that his father died several years previously of some obscure stomach trouble (probably malignant). V. R. E. equals L. P. V. L. E. equals 20/30 — .50 S equals 20/20. No external evidence of disease. Ophthal-

moscopic examination of R. E. reveals severe advanced type of neuroretinitis with macular exudations probably going on to atrophy. L. E. shows beginning of papillitis. Tension R. E. equals +1 (palpation). Clinical examination shows no evidence of any sinus involvement. Sent to hospital for treatment.

June 16th. After several days' treatment at hospital with pilocarpin sweats and eliminants, the whole right eye is acutely inflamed (uveitis). Excessive tension and eye very painful at times. Applied leeches to right mastoid.

June 21st. Right eye comfortable and inflammation apparently slightly less. V. L. E. equals 20/20. During this time urinary, blood, heart, chest, and general systemic examinations have been carried out, all with negative findings.

July 1st. Possibly slight improvement in appearance of right eye. Subconjunctival injection 15 minims 1-5000 cyanid of mercury with ½ of 1 per cent acoin.

July 7th. Stopped mercurial inunctions which had been used for some days and ordered sodium salicylat grs. 15 every three hours.

July 9th. Inflammation right eye improved.

July 11th. Another subconjunctival injection.

July 16th. Papillitis in left eye almost cleared up.

July 28th. Inflammation right eye slowly, but steadily improving.

August 5th. Dismissed from hospital and sent home to Gaffney, S. C. Right optic disc very edematous, pale, and elevated about 3 mm.

August 26th. Suspicion of exophthalmos, R. E. Sclera still much congested. Anterior chamber shallow. Pupil 4 mm. diameter. Nearly entire visible fundus white, hazy, and elevated three to four mm. Is this a neoplasm originating in optic nerve?

September 10th. Large white area with heavy bunches of vascular formations seems to be growing steadily in right fundus now occupying almost the whole visible fundus and best seen with +13 lens, indicating elevation of over 4 mm. Eye, of course, is totally blind. (At this time I advised an enucleation of the eye with a probable diagnosis of malignant growth and a suggestion for a consultation. Dr. G. E. de Schweinitz, of Philadelphia, was consulted with the result that he concurred in my advice as to an enucleation, but differed in the diagnosis as stated above in this article. Previous to this time von Pirquet and subcutaneous tuberculin tests had been made under my direction with negative results)

October 24th. The right eye was enucleated by the writer. At this time the tension had increased to such a point that in places it was evidently telling on the integrity of the eyeball, and the elevation of the growth in the fundus was 5 mm. (The macroscopic appearance of the bulb and severed nerve is referred to in the previous part of this article. As stated above, an error on the part of the pharmacist in supplying a solution unfortunately ruined the eyeball for microscopic examination, and indeed even for gross examination. This was a serious loss, as opportunities for such examinations in this type of case are undoubtedly rare.)

November 16th. Uneventful recovery from operation with good movable stump for prosthesis. V. L. E. equals 20/15.

December 1st. Prosthesis fitted. (Patient has been wearing artificial eye comfortably ever since. There have been no subsequent evidences of trouble in the right orbital tissues.)

Here follows history of left eye from this date:

January 25th, 1913. Patient complains of slight asthenopia left eye. V. L. Equals 20/20—, corrected with —.25 cyl. 45° equals 20/15. The fundus appears normal.

May 1st, 1913. Left eye, fundus appears normal except perhaps slight haziness at the edges of papilla and rather large veins. V. equals 20/15 with correction.

October 6th, 1913. Retinal venous engorgement and papillary haze. Vi-

sion with —1. cyl. axis 180° equals 20/20. Advised refraction again.

October 13th, 1913. Slight conjunctival congestion. Vision with correction equals 20/15. Ophthalmoscopic examination negative.

October 13th, 1915. Mild acute conjunctivitis, recovered in a few days. Fundus normal.

May 20th, 1916. Vision with correction equals 20/20. Fundus normal.

October 3rd, 1916. Slight asthenopia. Homatropin refraction shows net correction to be —.50 s. ⌒ —.50 cyl. axis 160°. This was not a satisfactory examination and I did not accept results as conclusive. Ophthalmoscope shows retinal congestion, whitish glistening corrugations and roughness in region between papilla and macula and suspicion of stellate streaks about macular region. Macula not marked. Excessive formation of fibrillary blood vessels, very tortuous, in this region. Vision with correction (before using homatropin) equals 20/30. Advised examination of heart and kidneys.

October 4th, 1916. Vision with —1. s. ⌒ —.50 cyl. axis 180° equals 20/20, minus. Dr. Jordan reports heart and kidney examination negative.

October 7th, 1916. Retinal vessels less congested.

October 19th, 1916. Acute follicular tonsillitis.

October 21st, 1916. Eye and throat better.

October 26th, 1916. Fundus still improving.

November 8th, 1916. Double tonsillectomy.

November 27th, 1916. Vision —1. s. equals 20/20. Ordered constant. Fundus same as last examination. It will be seen that there has been a gradual increase in refraction from —.25 cyl. a little over four years previously to —1. s. in November, 1916. I am inclined to think, therefore, that the clinical signs in the fundus may be explained as accompanying a mild progressive myopia.

Dr. de Schweinitz was again consulted at this time, at an interval of two months after I had last seen the case. At this time he wrote me as follows: "The large stringlike band of white tissue about the disc and the oval hemorrhages made me think, in view of the condition (which had previously obtained), of the other eye, that an early proliferating retinitis is beginning." To this letter I promptly replied that when I had last seen the patient two months previously, neither of these lesions were present.

On January 31st, 1917. Dr. de Schweinitz wrote me suggesting a probable diagnosis of tuberculosis as referred to in the first part of this article.

February 12th, 1917. I again saw the patient and noted in the fundus "suggestions of proliferation" along the upper sweep of one or two of the temporal vessels. This was somewhat in the nature of hazy sheaths running parallel to the vessels, but the "stringlike" bands observed by Dr. de Schweinitz had disappeared. The patient was put on increasing doses of iodid of potach and vichy water, and was allowed no use of eye for near work.

March 26th, 1917. In the extreme upper field of fundus are several patches of what look like spots of choroiditis with some pigmentary deposits and crossed by an evidently adventitious and tortuous vascularity. The suspected proliferative signs along the upward sweep of the vessels still persist. The patches above referred to can only be seen on wide dilation and extreme rotation of the eyeball.

April 4th, 1917. Taking 24 grs. KI, t. i. d. Choroidal patches plainly smaller and less congestion about them.

April 10th, 1917. Lesion in upper fundus smaller and less marked. V. L. E. —1. s. equals 20/20+.

April 16th, 1917. Patches in upper fundus smaller and show less vascular disturbance. Just to nasal side of these patches is a fresh hemorrhage about one-eighth size of the disc.

May 2nd, 1917. Patches less marked. Hemorrhage one-fourth size of disc. V. equals 20/20 —, with correction Now taking KI 50 grs., t. i. d.

The apparent hemorrhage persisted for several months, but seemed to be

reduced in size, altho remaining a bright red. In October, 1917, in the course of an X-ray examination of all of the sinuses, a diagnosis of an old mastoid involvement of the right side was made. In November, 1917, the mastoid was opened with the findings referred to in the first part of this article.

At the present time, April, 1918, the eye is quiet. Vision, with correction, equals 20/15. The patches in the upper fundus are much smaller. There is some tortuosity of numerous small vessels. The faint parallel streaking persists along one vessel in the upper fundus, and the apparent hemorrhage, which is now not more than 1 by 3 mm. in size (ophthalmoscopic magnification), still remains as a bright red spot. I have come to the conclusion that this is not a hemorrhage, but a small aneurism. All treatment has been discontinued, but the use of the eye for near work has been restricted and the patient will be kept under observation from time to time.

Note: It would seem that this interesting case was one of true hyperplastic exudative retinitis of nonhemorrhagic origin in the right eye, evidently not a malignant growth as subsequent events have proved; and in the left eye one of the "allied forms" of the same disease to which Coats has referred. Evidently the vigorous treatment with iodid of potash was of decided benefit, for the process has undoubtedly not only been checked, but has undergone at least partial resolution.

Case II. April 25th, 1916. Mr. S. W. F., Newry, S. C. Age 30 years. Farm overseer. Three days ago noted sudden diminution of vision of left eye. Has had frequent, but not severe pain "behind eyes." Had fall on back of head about one year ago, stunning him. V. R. equals 20/20 no acceptance. V. L. equals 20/200 no acceptance. Homatropin and retinoscopy show practically emmetropia. Ophthalmoscope shows slight fluffiness of papilla, left. Faint yellowish reflex over macular area. Tension normal. General health excellent. Positively denies specific history. Does not use tobacco or alcohol. Left pupil slightly larger than right. Does not react as well to mydriatic. Possibly intracranial tumor or ruptured vessel. ℞ KI in increasing doses.

May 1st. V. R. equals 20/20. V. L. equals F. 4 feet. (Central vision. He seems to have a fair eccentric field.) Ophthalmoscope, left, shows a disc of white over macular region, about size of papilla; hazy edges and a few minute vessels, not elevated. I noted a peculiar faintly yellowish reflex at this point a week ago. Evidently a tumor. Continue KI. Wassermann reported negative.

May 12th. Same as May 1st. General examination, including chest, heart, kidneys, etc., by competent clinician, negative. Continue KI.

May 26th. Exudate is irregularly oval and somewhat lobulated. No longer any traces of vessels on this formation. Seen clearest with a —2. lens in ophthalmoscope. Evidently subretinal. Whole fundus slightly hazy. Taking 32 drops KI, t. i. d. Ordered continued increase. The exudation above referred to is about the diameter of the disc horizontally, and a little over half of this measurement in the vertical line. I think undoubtedly one of the rare cases of massive exudation of the retina.

June 2nd. V. L. equals 20/200, eccentric. Macular patch undoubtedly smaller, being less than a disc diameter horizontally and less than one-half of this vertically. Considerable dustlike opacities in vitreous suggests choroid involvement. Now taking 46 drops KI t. i. d. Continued treatment.

June 20th. Improving. Exudative mass about one-half size of a month previous, about same general outline. Shades off at periphery as if undergoing absorption. Now taking 80 grs. KI t. i. d. Continued at 80 grs. for ten days.

July 1st. V. L. equals 20/200, eccentric. Exudate slowly absorbing. White glistening area less than one-fourth former size and somewhat triangular shape shading off over original area into normal retina. Decreasing

dosage from 80 grs. KI. Continue atropin and protection.

July 15th. Few sparse punctate glistening retinal spots just above central fundus. Cholesterin? Central lesion slowly absorbing with slight tendency to pigmentation. Patient again declares absolutely no tuberculosis has ever existed in any branch of family. V. L. equals 20/200 (not central).

July 22nd. V. about the same as a week ago. Exudate still clearing. Pepper dust opacities in vitreous persist.

Aug. 4th. Only small pigmented spot about size of split pea (ophthalmoscopic magnification) at macula. Slight pinpoint vitreous opacification. Discontinue KI for two weeks and start again.

Sept. 1st. Left macula steadily clearing. Small pigmented spot remains. V. equals 20/200, eccentric. Minute vitreous opacities.

Sept. 15th. Improving steadily. V. R. (eccentric) equals 20/200. Had to stop KI week ago for saturation. Resume next week. Left macula now appears as having faint, grayish appearance, in size one-half diameter of disc horizontally and one-third disc diameter vertically; ovoid, and at lower center a darkly pigmented spot.

Oct. 6th. V. L. +1.s., (atropin) equals 20/200, eccentric. Vitreous clearer; macular condition about same as last visit.

Nov. 2nd. Macular patch smaller and less distinct. Now of more regular ovoid shape, and about one-eighth area of disc in size. Dismissed for two or three months.

Note: There can be no doubt that this was a case of exudative hyperplastic formation of organized tissue. The unusual opportunity was here presented of observing the clinical development from the time vision was first seriously impaired by what was evidently a retinal or subretinal fibrinous or plastic exudate, to an organized vascular formative period, and on to final partial retrogression, with undoubted permanent functional impairment. At no time was there the slightest trace of hemorrhagic phenomena participating in the origin or growth of the lesions. The patient did not return as instructed, but the reporter is endeavoring to get in touch with him.

Case III. November 30th, 1915, Mr. D. C. C., aged 35 years, bookkeeper, complains of asthenopia, frequent styes and chalazia; wearing: R. +1. cyl. 90°; L. +0.75 cyl. 90°. V. R. equals 20/20 +1.50 cyl. 90° equals 20/20. V. L. equals 20/70 +1.50 cyl. 90° equals 20/20. Retinoscopy checks this finding. Ophthalmoscopic examination negative, except perhaps rather hazy discs.

Dec. 7th: V. R. equals 20/30 +1.50 cyl. 90° equals 20/20.

V. L. equals 20/200 +1.50 cyl. equals 20/50. R. fundus somewhat congested and slight "knobby" appearance of papilla. L. fundus shows papilla markedly "knobby" and gray and white mottled, much like a piece of popcorn, with faint suggestion of vascularization. Apparently exudative (?) condition around papilla and latter is distinctly elevated (about three diopters). "Massive exudation of retina." (?) Ordered Crookes' glasses and advised careful watching and further examination. (This patient was of the neurotic type and became dissatisfied when I told him his trouble might be serious. He did not return after this second visit, altho his family physician made every effort to get him to do so. Eighteen months later his physician told me he was complaining sorely of his eyes, but would do nothing for them.

Note: This case, in the space of seven days, showed a transition from slight papillary haze to a well marked organized tissue formation without the slightest evidence of hemorrhagic antecedence. Nor had his family physician—a very capable man—ever suspected lues.

Case IV. September 29th, 1917. Mrs. W. M. E., Honea Path, S. C., housekeeper, aged 55 years. Vision has recently been failing. No pain or inflammation in eyes. General health good. For some years has been wearing reading and distance glasses, fitted by opticians; the present ones recently fitted. V. R. equals 10/200 —2. s.

equals 20/100. V. L. equals 20/20 and no improvement with any glass.

Ophthalmoscopic examination reveals in the right eye a very edematous retina with a few bright yellow spots (cholesterin?), one to two millimeters in diameter (ophthalmoscopic magnification), in macular area, and between that and disc. The disc is surrounded by an area of white with grayish clouding (probably edematous infiltration). There is a persistent canal of Cloquet, the anterior end of which is quite opaque. Tension normal (palpation). Left eye edematous retina and disc. Tension normal. There is no sign, symptom, or history of syphilis, tuberculosis, or trauma, and no indication of hemorrhages.

October 12th. Ophthalmoscopic appearances about same. Patient's family physician reports heart, kidneys and blood pressure normal, and patient otherwise sound. V. R. —2. s. equals 20/100, V. L. equals 20/20.

Examinations on November 30th and January 1st, 1918, show little change.

February 1st, 1918. Increasing infiltrated area around disc, right eye, being more pronounced at temporal side, where it is about two-thirds of a disc diameter in width and somewhat narrower on nasal side of papilla. The appearance of the infiltration presents the popcorn or cumulus cloud effect, and is best seen with a —5 lens in the ophthalmoscopic aperture. Fine vascularization is noted. The left eye shows indications at temporal border of disc of the same process commencing as obtains in the right eye. The patient has no teeth. A careful examination of the nose and paranasal sinuses is negative. There are, however, small diseased tonsils, exuding pus on pressure. V. R. —5. s. equals 20/100 (note myopic increase). V. L. equals 20/40, no improvement with any lens.

March 1st. V. R. —5. s. equals 20/100, V. L. equals 20/30. The exudation about the right disc is bulging out still more in temporoinferior area. In left eye the exudate now encircles the disc in a band about one-eighth disc diameter in width. Attached to the nasal side of this band is a thin, finely organized opaque veil like substance, presenting edgeways in the vertical plane, about one-half disc diameter in vertical width, and waving in the vitreous. The appearance suggests proliferative retinitis, with a suspicion of fine spun vascularity. Patient is just recovering from an intercurrent attack of bronchitis.

March 27th. V. R. —5. s. equals 20/70, V. L. equals 20/30. Fundi about same.

March 28th. Double tonsillectomy; local anesthesia.

May 3rd. The organized exudate about the right disc is increasing, being now a full disc diameter in width temporally and inferiorly. There is undoubted fine vascularization. From the hyperplastic mass, spreading for two-thirds of the way to the macula is a whitish haze of exudation, roughly triangular in shape with base the width of the new growth, beneath the nerve fiber layer and with characteristic appearance of serous retinitis, evidencing the extension of the exudative process. Organization of this exudation can be seen to be taking place along the course of some of the vessels, contiguous to the already organized mass. Tortuosity of vessels elsewhere in retina. Increased evidences of degenerative changes in macular area, and between that and disc. Several irregular bright yellow spots of varying sizes and shapes are noted, and in some are faint appearances of pigment deposits in centers. Growth and fundus best seen with —7 lens. The left fundus shows marked tortuosity of vessels. The proliferating tissue at nasal side of disc is appreciably less well defined and seems to be atrophying. V. R. —7. s. equals 20/200+, V. L. equals 20/30. Tension (Schiötz tonometer), R. E. equals 18, L. E. equals 18.

Note: There is an evident increase in the anteroposterior diameter of the right bulb, in marked contrast to the behavior of the left bulb, tho the pathologic process in each eye is clearly progressing. This phenomenon, it seems to the writer, can only be explained on the ground of the exertion of traction posteriorly by the process

as it extends backward along the nerve trunk. There is no evidence of lenticular swelling or keratoconus. The lesion at the disc could not possibly be confused with the socalled posterior staphyloma of progressive or high myopia, which, it is now recognized, is not a staphyloma at all, in the real sense of the word. The whole history and picture would confound the suggestion of such confusion, tho perhaps the writer's inadequacy of description might incite such a criticism.

CONCLUSIONS.

There is a retinal pathologic entity consisting of organized hyperplastic tissue evolving from fibrinous or plastic retinal exudates of indeterminate origin.

These exudates are not of hemorrhagic character, tho it would appear that they must necessarily have a vascular pathogenesis; and the tissue into which they are determined would seem to be analogous to granulation or chronic inflammatory tissue.

The clinical phenomena manifested can evidently be divorced from syphilitic, tubercular, or traumatic causation, tho unquestionably resembling the lesions sometimes seen consequent upon these origins.

The hyperplastic organizations are characterized by a white or grayish or yellowish or mottled appearance, in form suggesting a piece of popcorn or miniature cumulus clouds, showing a fine vascularity at some period of their development; of no fixed size; usually, it would seem, in one mass, often highly elevated from the retinal level; when in the active formative stage usually with well marked peripheral definitions; with a minimum of pigmentation or none at all; and, in the writer's observation at least, with points of selection for their development either in the papillary or macular area. If in the disc area the organized exudates probably always extend along the nerve trunk beneath the sheath. They are, of course, essentially benign.

As the pathologic morphology and clinical appearances of these lesions are evidently similar (tho usually distinguishable by location, arrangement, anamnesis, and instruments and methods of precision), to those of retinitis circinata, retinitis proliferans of nonhemorrhagic origin, and certain forms of syphilitic, traumatic and perhaps tubercular retinitis, it would seem appropriate for clinical study and for the minimizing of a certain obscurity, to group all of these, for differentiation from other types, under the descriptive head of Hyperplastic Exudative Retinitis—Nonhemorrhagic.

NOTES, CASES AND INSTRUMENTS

OCULAR ACTION OF DICHLORETHYLSULPHID (MUSTARD GAS).

CAPT. H. L. PICKARD, M. D.

EDGEWOOD BASE HOSPITAL.

This is a preliminary report on the action of mustard gas in man, as seen at the Edgewood Arsenal. Authority to publish granted by the Board of Publication, Surgeon General's Office.

The reactions in the eyes to dichlorethylsulphid depend upon the duration of the exposure, and the dilution of the gas. Many of our cases were exposed for a period varying from one to thirty days, to the air contaminated by the gas in the plant where the dichlorethylsulphid was manufactured.

The continual leaks would have a varying effect upon the men, depending to some extent upon their susceptibility. Eyes once affected by the gas seem more prone to a second attack, and the period between attacks grows shorter, as the men are returned to work. Some cases exposed to the vapor or fumes leaking from pipes or stopcocks, would become affected with smarting of both eyes in from one to six hours. Many of the men would continue work during their shift, go to their barracks and to bed, be awakened during the night with intense pain and report to the hospital in the morning. In some cases where the gas would escape in jets as from manometers, rubber tube attachments, etc. and the face sprinkled with the chemical, the reaction would be immediate, and result in severe burns. Our cases ranged in severity from the mild conjunctivitis, with slight lacrimation and photophobia and only slight injection of the conjunctivas, radiating from the limbus in a triangular area toward the inner and outer canthi, and the width of the palpebral fissure, with pearly white conjunctiva above and below, to the high grade conjunctivitis associated with edema of the lids and chemosis.

The conjunctivitis has been arbitrarily divided by us into the mild, medium and severe forms.

The mild form shows only a slight degree of injection of the triangular area above mentioned, with very slight or no lacrimation but a decided photophobia. The photophobia seems to be marked from the incipiency of the attack, and the pain is usually of a smarting nature. The cornea clear, pupils small, active to light and accommodation, and the iris negative.

The medium cases show congestion of both the ocular and palpebral conjunctivas, with the straight scleral vessels engorged and tortuous, and the very fine vessels visible. Here the lacrimation is profuse and the photophobia intense and associated with blepharospasm. The lids may be glued together by the secretion but this is rare as the secretion is watery and seems to be more lacrimatory, and unaccompanied with a thick viscid discharge. No hemorrhages are visible, but the vessels seem on the point of rupture.

In the severe form, edema of the lids is marked, and the predominating symptom. In some cases the swelling of the lids is on a level with the supraorbital ridge, and extends to the nose. On forcibly retracting the lids, the secretion squirts from the eye onto the cheek, in clear, colorless, limpid droplets, which rapidly reaccumulate. The skin is red, tense, hot and the patient complains of pain in the skin and the eye.

The conjunctivas are intensely injected, both palpebral and ocular, chemosis is present and minute hemorrhages, scattered in the lower segment of the ocular conjunctiva, toward the culdesac, rarely above the median line and we have yet to see a hemorrhage on the palpebral conjunctiva.

In this variety the photophobia and lacrimation is intense, blepharospasm continuous, and the oculodynia of a high grade. The cornea remains unaffected and with the fluorescein test is negative. Pupils remain small, active to light and anterior chamber negative.

Our first cases were treated with rest in bed, cold compresses, cocain for the first day, once or twice; atropin twice daily. These cases remained in the hospital for from three to six weeks, depending on the severity of the reaction.

Latterly we have been using cocain for only one instillation, and for its immediate quieting effect. Atropin, three times daily for its continued physiologic effect, cold compresses, boric acid flushing, iodoform powered into the eye twice daily, yellow oxid of mercury salve to the lids and a Liebreich bandage for from three to seven days, or longer as the case requires. Under this plan of treatment, the stay of patients in the hospital has been decreased to seven to fourteen days, with rapid amelioration of all symptoms.

It is our opinion that the deleterious effects of dichlorethylsulphid upon the eyes, can best be treated by antiphlogistic measures, ignoring to a considerable extent the chemical composition of the affecting gas. To look for a chemical antidote to neutralize its action in the eye, would more than likely lead to a substance as severe in reaction as the poison itself, whereas, by treating the inflammatory symptoms, immediate relief is obtained, insofar as pain, lacrimation, photophobia and swelling are concerned. Previous to the use of the mercurial salve externally, about five (5%) per cent of our cases developed chalazia, hordeola and small multiple abscess of the lids; but since its introduction into our routine treatment, we have had no such complications.

SCLERITIS AND EPISCLERITIS.

HUGH MILLER, M. D.

KANSAS CITY, MO.

These notes were read in connection with the presentation of a case before the meeting of the Kansas City Eye, Ear, Nose and Throat Club, October 17th, 1918.

The etiology is somewhat obscure and probably from a constitutional disturbance rather than a local affection. We find in literature that the following are causative factors: Rheumatism, tuberculosis, syphilis, menstrual disturbances and others.

Rheumatism itself has been obscure in etiology. We now attribute as a causative fact of rheumatism toxic absorption principally from the oral cavity, pyorrhea and tonsils. So we would at this time say simply toxic absorption. It is a question whether we have true scleritis and episcleritis from tubercular bacilli. As to syphilis I have been unable to find any literature definitely showing characteristic scleritis except where it is secondary to iritis or keratitis.

That it may be from menstrual disturbances I have doubts. I have had but three cases in my experience, two in men and one woman; in the latter there were no indications of genital disturbances. The tonsils and dental pyorrhea are the places where we should seek for an explanation of these conditions. I am quite confident that scleritis is a local manifestation of constitutional absorption of toxins. Our most recent observations in toxic absorptions are explaining many pathologic conditions that previously were obscure.

Objective Symptoms.—We find some millimeters from the cornea a hyperemic area with an elevated slate colored center. There may be one or more of these areas at the same time, on the same eyeball. Seldom are both eyes involved at the same time. These areas are variable in size and shape, depending upon the intensity of the disease. It may be simply episcleritis, involving only the tissue covering the sclera, or it may extend thru the entire thickness of the sclera, in fact include the choroid as has been shown by microscopic investigation.

Subjective Symptoms.—Dull, heavy ache is the usual nature of the pain. Sometimes sharp shooting pain. The pain is produced principally by pressure, as I desire to show further on. There is lacrimation and slight photophobia. The diagnosis is made by the inspection of the eye, where we find the characteristic areas.

Progress.—The healing of one area requires from two to six weeks. Oftentimes before the first has recovered, a second or third inflammatory area has

appeared, which may be near the original site or on any part of the anterior hemisphere of the globe, usually several millimeters posterior to the border of the cornea. It is known to be recurrent and chronic and to run on several years. Prognosis is favorable as to sight, provided the intraocular tissues are not involved. When the choroid, ciliary body, or iris becomes involved, prognosis is unfavorable.

Sequels.—After the inflammatory period is past there is left in episcleritis simply a dusky area. But in scleritis the conformity of the globe has changed. In one case I had, an anterior staphyloma appeared at each point of the inflammatory area. The inflammatory process had almost completely encircled the globe so that these nodules reminded one of a potato, that had taken second growth. There may still be vision in eyes that have had such inflammation, but the irregular astigmatism produced is next to impossible to neutralize.

Treatment.—Treatment in our text books has principally followed the lines of that suggested by etiology. I believe now that we should look for some local source of the infection with a purpose of shortening the course of the disease. I desire to present a case to-night for the purpose of bringing out some points in the foregoing discussion:

Case.—Mr. G. F. of Kansas City, Mo., came to my office September 7, stating that he had had a cinder removed which had been buried in the sclera. The eye was still painful and he desired that I ascertain if there were more foreign particles. I found but a red area and no remaining particles of cinder. I dismissed him feeling that there had probably been a foreign particle embedded. This original area I now believe, was simply the beginning of his present trouble; and there probably had been no cinder there at all, but the small and darkened spot had the appearance of a foreign body which some one had attempted to remove.

On the 29th of September he presented himself to me in great pain. I found deep episcleritis or scleritis near the site of the former area, and sent him to the hospital. For a week following September 29th he suffered great pain, notwithstanding he was taking fifteen grains of salicylat of soda every four hours, and atropin instilled in the eye every six hours. He finally became easier. The above drug kept him quite comfortable. About October 10th he had another flare up, pain exceeding that which he had had on the previous occasion, when on inspection I found this second area beneath the upper lid. Saturday morning, the 12th of October, I operated on this last inflammatory area.

The operative procedure was as follows: After dissecting freely the conjunctiva and episcleral tissue down to the dark elevated area I transfixed it with a fine cutting instrument. It is necessary that the transfixing instrument enter at a tangent to the eyeball. Promptly the discoloration disappeared (five days later the bluish discoloration reappeared, but it is a flattened area instead of a tumor as before). I dressed the eye with a pad of gauze and put the patient to bed.

In a brief survey of the literature I have not found any describing this procedure for scleritis. While it is a new idea I felt it was a rational one and at least could do no harm. Tho this operation may not prohibit attacks in other locations of the sclera or hasten complete recovery it would seem to lessen the danger of extension toward other internal ocular structures.

The operation gave instant relief from pain, and the patient has had perfect comfort to the present time. Before the operation drugs only partially relieved the pain, since then none has been necessary. I can most certainly recommend the procedure so far as the comfort of the patient is concerned. The influence on the disease is yet to be determined. As to this patient's tonsils, they are to be removed at an early date and I hope to make a further report on the case.

REPORT OF COMMITTEE ON STANDARDIZING TEST CARDS.

Presented to the Section on Ophthalmology of the American Medical Association, June 14th, 1918.

The work of your Committee for the past year has been done on the figures designed for the testing of those who are not familiar with the letters of the various alphabets. Essentially the same plan of comparative testing of the different figures was used. Over 180 different figures have been tested, the collection and preparation of these figures having been done by Dr. Ewing.

The Committee has thus selected the accompanying characters from among the various designs which heretofore have been submitted by authors on this subject.

Small variations in the size of letters would be subject to criticism because of incongruity to the eye, but small variations in the size of the figures here considered are not noticeable: provided the figures are well proportioned and are arranged to line up evenly with one another. The choice is based on the following principles:

(1) The lines of which the chief frame work of the character is constructed should each subtend the angle of one minute.

(2) The main body of the character should conform to the five minute visual angle.

(3) Slight unobtrusive variations may be made in the lengths of the lines of the characters beyond the five minute angle, in order to insure legibility: as it is practically impossible to construct pictures of ordinary well known objects in the five minute space with lines of one minute thickness.

(4) Masses of black are undesirable.

(5) Finer lines than subtend the angle of one minute are to be avoided in the body of the character.

(6) As any one character cannot be depended on for a visual measurement, the smaller characters for distances less than 20 meters should be arranged in rows of three or four each. The reading of the row is considered by the Committee to be the equivalent of V=1.

The interval may be in any ratio, but the geometric ratios of Green, are suggested as being the most advisable.

The characters suggested by the Committee are those indicated in the accompanying diagram. They consist of the ring, square, star, pitcher, cross, horseshoe, flag, fork, and chair. They should be printed in black on a creamy white background and the paper or board should be of sufficient hardness to prevent the type sinking into it.

There is a distinct advantage in having a relatively small number of these characters repeated on successive lines of the chart. Because in this way it

Figures suggested for testing illiterates, recognized at 5 meters by V-1.

can be known from the larger lines whether the person tested understands, and responds properly to the test.

The characters suggested by the Committee are for subjective tests to meet the requirements of useful vision. They conform so well to the letter tests that the two may be readily interchanged.

In addition to the characters here presented, the several more accurate tests, ordinarily designated as "one minute" tests in contradistinction to the five minute tests, have been considered.

These are the Snellen "E," the Landolt "Broken Ring," the Jackson "Incomplete Square," the "E" and the Incomplete Parallelogram forms of Pergens, also the several varying one to

three minute tests of Pergens, the "Cross-point" and "Line-point" tests of Wolffberg, and the Central Broken Line test of Ewing. Taken singly each of these tests is practically the equivalent of the others. They are excellent for employment in the final checking up test, when there is any question of a fine degree of visual acuity involved; and for the repeated testing of persons with greatly reduced vision.

The trouble with each of them is that the location of the "one minute" test must be indicated either by pointing to it, or by naming the position in which it is to be placed. This, including the instruction with regard to the test which must be given the patient, requires a greater amount of time than the simple naming of a test object. However, the Committee recognizes that these "one minute" tests are necessary for the exact comparison of the vision of the same eye at different times, or of one eye with that of the other, or for comparing the exact vision of different individuals; and advises that every ophthalmologist have one or more of them on hand in case special accuracy is demanded.

For obtaining an idea of the vision of very young children the Committee indorses the suggestion of Worth, that balls of various sizes be employed. However, in place of the ivory which is used by Worth, a noiseless material as paper, yarn, cork, or rubber painted white or black to contrast with the background would be superior for the construction of the balls.

Semaphores are special tests for railroad and signal service employment, although they may be considered tests for the illiterate. The Committee recommends those designed by Dr. Charles H. Williams and by Dr. N. M. Black.

Nelson M. Black,
Walter B. Lancaster,
A. E. Ewing.

SOCIETY PROCEEDINGS

NETHERLANDS OPHTHALMOLOGICAL SOCIETY

FIFTY-SECOND MEETING

Dr. C. Nicolai in the Chair

Translated from the Nederlandische Tijdschrift v. Geneeskunde, March 16, 1918, by E. E. Blaauw, M. D.

Experimental, Toxic, and Anaphylactic Inflammation.

F. Wibaut starts from Kümmel's investigation to produce inflammation in the rabbit's eye thru anaphylaxis. He describes the pathologic-anatomic changes found in his experiments. He found a moderate inflammation in the iris, especially at its posterior surface, a much more severe inflammation in the ciliary body, and extensive diffuse and focal inflammations of the choroid. He mentions destruction of the retina, slight changes in the vitreous, and in the choroidal foci mononuclear leucocytes with epithelioid and giant cells.

Kümmel concluded that these inflammations greatly resemble sympathetic ophthalmia; that these investigations prove that focal inflammations in the uvea do not need to be of bacterial origin; that if blood or pieces of tissue of sufferers of sympathetic ophthalmia produce inflammation in the rabbit's vitreous, this may not lead to the conclusion of the bacterial origin of sympathetic ophthalmia.

Von Szily, Adalbert Fuchs, and Meller protested especially against the first conclusion of Kümmel. Repeated experiments gave in general similar results, from which they, however, draw different conclusions. They are inclined to consider the changes due to the first injection. The inflammation is then in general toxic, and has the character of an *endophthalmitis septica* (Meller); but this Wibaut rather calls a hyalitis. It is the picture of a very serious inflammation of the ciliary body, especially of the tops of the processes; the retina is severely af-

fected and often destroyed. Serious changes in the choroid are also found, the more as the retina has suffered. If the retina was not affected or previously detached, the choroid was least affected or not at all. And if an exception is found, Meller reduces this to particular circumstance of the specimen. The giant cells he found are "foreign-body-giant cells" formed around tissue fragments, and especially pigment granules. The *"anaphylactic ophthalmia"* corresponds with the endophthalmitis septica in the following points: 1. The exudative character; and affection chiefly of the ciliary body, especially of the tops of the processes, and the retina. 2. The change of the exudate into connective tissue with formation of "Schwarten" with retina and ciliary body, and the appearance of large cells, as epithelioid and giant cells. 3. The dependence of the affection of the choroid on that of the retina.

Meller does not consider these changes as anaphylactic, but considers them more as depending on the poisonous character of the serum of the first and second injections. Among the described eyes there is, however, one which even to him has shown anaphylactic phenomena. The first injection was in the vitreous and a renewal of the inflammation followed an intravenous injection. The iris was found richer in cells with nodular foci and plasma cells, moderately strong exudation of and infiltration with round cells in the ciliary body. The retina has suffered only in its fine texture, the choroid contains more cells than normal; the cells lie in groups, chiefly plasma cells, with tendency to break thru the pigment epithelium. The optic nerve is inflamed and the choroid shows in its neighborhood more changes than elsewhere.

Wibaut used for first and second injections freshly sterile horse serum. After injection of this in the vitreous, a rabbit's eye shows only in the first days a slight vitreous opacity and slight hyperemia. An eye injected three days ago with 0.2 cc. horse serum shows large fluid-blebs in the epithelium of the cilary processes, the fluid contents of which are somewhat strongly stained and contain some remains of the vitreous.

The anaphylactic inflammations were produced by a first intravenous injection followed, after an incubation time of some 14 days, by one single injection in the vitreous. After 24 hours rather regularly a severe inflammation is found with much exudate in the anterior chamber, deposits on the membrane of Descemet, swelling and hyperemia of the iris, and formation of synechia. The fundus is hardly seen thru vitreous opacities. An eye enucleated 5 hours after injection shows, as the only change, blebs in and below the epithelium of the ciliary body. These are to be considered a beginning of exudation.

At 24 hours after the injection the eye showed the clinical signs of very severe iridocyclitis. The cornea was nearly normal. The anterior chamber contained polynuclear leucocytes and lymphocytes, many with pigment granules. The exudate formed also some spots on Descemet's membrane. There was the commencement of infiltration at the pupillary margin, and a little more at the irisroot. The ciliary body showed extensive inflammation. The ciliary processes were much thickened, and in all folds was formed exudate.

The thickening was partly due to infiltration, with strong hemorrhagic diapedesis, partly to edema. The infiltration contained chiefly polynuclear leucocytes, but the mononuclear elements began to show. The hemorrhagic diapedesis was so great, that at first view one thinks of an extensive hemorrhage. But tissue elements between the red blood cells diffusely dispersed, proved the contrary. The superficial as well as the pigment epithelium suffered severely in numerous places and were partly absent. The same blebs are found as in the first stages, but now filled with red blood corpuscles and exudate cells. Some few mononuclear lymphocytes in the vitreous. The choroid showed local thickenings thru

infiltration with mononuclear cells, with a small perforation of the pigment epithelium. The retina was normal. The sclera and the episclera tissues were much infiltrated; especially around the limbus, where was also a large focus with polynuclear leucocytes, and hemorrhagic diapedesis, which continued in the loose connective tissue of Tenon's capsule.

Another eye, also enucleated 24 hours after the second injection, showed a somewhat more advanced stage. An extensive exudate was in the anterior chamber, with many more mononuclear cells, and still more pronounced in the corneo-iridal angle. It comes in a stream from the pupillary space, but seems also to be formed by the anterior surface of the iris. A few Descemet spots. Hyperemia of the iris and infiltration of the pupillary margin, irisroot and in the deeper layers, where the ciliary processes originate. The ciliary body is more inflammed than in the foregoing case. The processes are filled with exudate, and also the crypts and folds. The mononuclear cells, chiefly lymphocytes, have become more numerous than the polynuclears; hemorrhagic diapedesis was found only in a few places.

The pigment epithelium had suffered seriously; in different places it was pierced by the exudate. In the surrounding tissues were found loose epithelium cells, with pigment free, pigment granular, and mononuclear lymphocytes, which have taken up pigment granules, slight exudate in the vitreous, a slight perivasculitis here and there in the retina, and some polynuclears at its surface toward the vitreous. A little exudate in the excavation of the optic nerve. A large focus was found in the choroid in the neighborhood of the ora serrata; and also in other places diffuse and focal conglomerations of mononuclear leucocytes, distributed thru the entire thickness of the choroid.

An eye enucleated three days after the anaphylactic reaction shows a picture resembling the foregoing, without polynuclears in the ciliary body. The retina was not much changed. In the excavation of the papilla there was a distinct papillitis. The choroid showed over its entire extent focal inflammations. Between the foci, the inflammation was less, or the tissue even entirely normal. Even the layers toward the sclera took part. Where the foci increase the pigment epithelium is often pierced and the leucocytes come outward. The retina is there lifted up, with damage to the cones and rods. Next the dark nuclei of the leucocytes were seen, much paler larger oval nuclei, which resembled the nuclei of the pigment epithelium.

Wibaut has shown with these specimens, that it is possible to produce inflammation along anaphylactic ways, which shows the picture of a rather clear uveitis. The focal appearance of the inflammation is rather remarkable, because a toxic agent was introduced, so that a diffuse inflammation could be expected. Wibaut thinks that Kümmel went too far, when he spoke of a great resemblance with sympathetic ophthalmia. But on the other side these pictures are very different from those of septic endophthalmitis. The second conclusion of Kümmel, that it is possible to produce a focal inflammation thru toxic means, is very important for our general pathologic thinking. Also the third conclusion will not find much opposition. A single injection of human serum in rabbit vitreous produces toxic conditions. The specimens resemble more the description of Kümmel and his critics, and indeed look very much like endophthalmitis septica.

Discussion. — Wolff would have liked to hear the name of Wessely, who first did excellent work regarding anaphylaxis of the eye.

Van den Borg asked if the neuritis must be regarded as directly anaphylactic or as secondary to the cyclitis.

Mulock Houwer asked how to explain the focal character of the inflammation.

Wibaut claimed no definite idea as to such explanation. Vessels are not always seen in the center of the foci, so they are not always perivascular infiltrates. He did not know that Wes-

sely already had done these experiments; he considered the neuritis as secondary.

Ocular Changes after Epidemic Cerebro-Spinal Meningitis.

G. TEN DOESCHATE examined 50 convalescents from meningitis. Twice he found a diminished vision 6/9 to 6/18, without fundus changes. In 8 cases paralysis of the accommodation was found, in 3 after 18, 17, and 10 months after the attack. Perhaps the accommodation disturbance depends on affection of the nasal cavities.

Spontaneous nystagmus was found in 25 of 48 patients. Some were free in the beginning, but the nystagmus appeared during the course of the rather long examination. Fatigue may have been the cause. Many of the patients, however, had labyrinthin-cerebellar changes, and other symptoms of the posterior cranial cavity lesions, so that an injury of the fourth ventricle, especially of Deiter's nucleus, may be surmised. Four times anisocoria was found and twice an irregular pupillary circumference. These and slight eye muscle changes might not depend on the meningitis. In one patient, however, an abducens paresis was found.

A distinct concentric limitation of the fields for white and colors was found in ten patients, and in four for colors alone. Three times this was combined with an enlargement of the blind spot, while in five cases fundus changes were observed. The light sense was diminished in three patients. Six times venous hyperemia and four times one sided redness of the papilla were seen. Choroidal changes were found in seven cases, mostly peripheric foci; and once a distinct atrophy of the anterior part of the choroid combined with hemeralopia. In all these choroidal affections labyrinthine changes were also found.

In four cases the papillary borders were indistinct with venous hyperemia, and once there was a greyish discoloration of the peripapillary region. Temporal atrophy with enlargement of the blind spot was seen once. Once in both eyes radial reflexes appeared around the macula lutea, while between the papilla and disc the reflexes were vertical. Vision, R. 2/60, L. 3/60. Abnormal pigmentations of the yellow spot were found twice. In one of these cases the macular reflex was a lying rectangle. In 35 patients the blind spot was mapped; with a 1 cm. object at 2 meters distance from the Bjerrum screen. Five times it was enlarged, once both, 4 times on one side. It was considered abnormal when the horizontal diameter was larger than 7 degrees.

The limits for white and colors were about the same. This may suggest an affection of some nasal sinus. With epidemic cerebrospinal meningitis, affections of the posterior nasal sinuses are found. The degeneration of the "peripapillary bundle" could then be produced by stasis or by toxins. But it could also be possible that noxious products from the cranial cavity penetrate in the intervaginal space of the optic nerve, whereby the superficial peripapillary fibers suffer the first and most. In the case where the blind spot was found enlarged in both eyes, both maculas were abnormal, while the disc margin was partly hazy. In one of the other patients the papilla was pale at the temporal side, which points to a more extensive affection of the optic nerve.

DISCUSSION.—Zeeman asked if the light sense disturbances were found with choroiditis or neuritis, and if the choroiditis and neuritis were found in the same patient.

Ten Doeschate found light sense disturbance with and without choroiditis. In the case with choroiditis and neuritis the blind spot could not be examined.

Signs of Graves' Disease.

W. P. C. ZEEMAN demonstrated a patient with remarkably distinct symptoms of Dalrymple and von Graefe, altho other symptoms of Graves' disease or of any other neurologic condition were entirely lacking.

Pulsating Exophthalmos from Multiple Myelomata.

W. P. C. Zeeman was prevented by her death a few weeks before, from presenting a patient whose clinical history he considered it worth while to relate. A 53 year old woman admitted in December, 1915, with an affection of the left optic nerve. Since a few weeks she had complained of a haze before the left eye. Wassermann positive. In spite of specific treatment her condition became worse. She returned home and was not seen again until the end of June, 1916. The eye was then blind, and had come slowly forward. The eye was proptosed to 7.5 mm., straight forward. The pupil was a little wide, and did not react to light. The disc was pale, especially at its temporal side, light was not observed. A probable diagnosis of orbital tumor was made, perhaps starting from the optic nerve.

As another antiluetic treatment was ineffective, operation was performed at the end of July after resection according to Krönlein. The exophthalmic globe was beginning to show pulsations. No souffle was to be heard with the stethoscope; the patient herself did not notice bruit. The diagnosis remained of an orbital process situated directly at the optic nerve, or an aneurism of the ophthalmic artery. The Wassermann reaction pointed toward the formation of an aneurism. It incited to special care, but could not be a reason for abstaining from operation.

Above the optic nerve a pulsating tumefaction could be felt; its form and course agreed with the location of the ophthalmic artery, and seemed to affirm that it was an aneurysm. Along the finger, a ligature was put before and behind with an aneurysm needle. The operation was done under local anesthesia. During manipulation a place of such slight resistance in the roof of the orbit was found, that an absorption thru the aneurysm seemed present.

During the first days after the operation somewhat more protrusion was present, considered as result of hemorrhage and reactive swelling. Large doses of potassium iodid were given, and after some months the protrusion had receded up to 4 mm. A radiogram showed the absorption that had been felt in the roof of the orbit. A year later she came back in bad condition; she was very weak and the protrusion had again increased. Albumin was found in the urine, and a circumscribed swelling of the left humerus was present; the diagnosis "multiple myelomata" was made. Death in the beginning of November. The autopsy showed the great extension of the myelomas. Within the cranium different ones were found, and at the roof of the orbit a large tumor-mass existed, which had eroded the bone. The vascularity of the tumor was sufficient to explain the observed pulsations.

Intermittent Exophthalmos.

Zeeman demonstrated a patient with intermittent exophthalmos, and the photographed displacements of the cornea under influence of different movements which hinder the venous flow. The cause of these orbital venous ectasias or varicoceles is yet unknown. Zeeman considers it not proven, and improbable, that the cause might be a narrowing of the jugular vein.

Cyclodialysis and Trephining in Buphthalmos.

W. P. C. Zeeman has performed 11 times cyclodialysis in five children. The first case was a decided success; but the results in the second, and third children were far less satisfactory, in spite of the fact that the operation was repeated in both eyes after a short but passing success, and of the third child the one eye was operated once and the second twice. Each of these children had important decompensation phenomena since birth, that is more than two years; and the condition was very unfavorable in spite of the use of pilocarpin since one half and one year respectively. In a fourth child the cyclodialysis made the cornea in the one eye clear and smooth; but a trephining of the sclera was necessary in the

other eye, on account of no improvement. In a fifth patient, where a trephining was done in the one eye with complete success, the other eye became decompensated in spite of two trephinings. A cyclodialysis produced at the end the wished for success, which has now lasted three years. V. = R. 1/60, L. 1/2, tension normal. In 11 cyclodialyses 3 times this result was reached. As far as clinically could be shown no damage was done by the operations.

Not satisfied with the above results, Zeeman performed trephining 11 times in 7 children. In three children the operation was done on both eyes, in the other 4 on one eye. A prolapse of the vitreous occurred during the operation twice. One was in a very large entirely blind eye, where ultimately it led to a slight decrease in size of the globe, which was an advantage cosmetically. It could perhaps have been prevented if after the small peripheral iridectomy, less handling had been done in making the toilet.

The second loss of vitreous occurred in a technically well executed case; the eye went to ruin. Twice a trephining was done in vain, both times on the same eye. This happened in a child, where one eye was operated with good success, but the operation failed on the other eye, and was repeated, also in vain. This eye had at the end normal tension after a cyclodialysis, and three years later the cornea and papilla showed that a sufficient normal equilibrium had been reached.

Eight operations (of the 11) were at first successful. In two, however, a complication has occurred. One was an 8-year-old boy, whose one eye was already long blind, and in his other only remained a small peripheric part of the visual field. Some time after the operation detachment of the retina occurred, which, altho remaining localized, had to be considered a very serious complication. The second case was a late infection, 5 years after the operation, serous hyalitis.

The retinal detachment seems to come from the continued and great lowering of the tension in the large and already old eye. As retinal detachment is known to occur frequently in old buphthalmic eyes, such a free drainage as the trephining seems undesirable in a large eyeball, and especially in older cases of buphthalmos. Zeeman thinks that operation should only be considered in very young children; and that the menacing retinal detachment alone is reason to desist from any operation in older children, and only in case of high necessity perhaps can be thought of sclerotomies after Snellen and Vincentiis.

Was the late infection preventable? Shortly after the trephining began its triumphant march, Straub modified the location of the connective tissue flap, parallel with and high above the corneal margin, which Elliot accepted in his second edition. His second modification was to prepare a thick conjunctival flap up to about 1.5 mm. above the corneal margin, and then a thin scleral flap until the corneal tissue shines thru; the conjunctival flap is thus strengthened with a thin scleral flap.

Undoubtedly, even less frequently than after Elliot's operation, a continuous drainage will be reached. But experience has shown that increase in tension is exceptional. Even if a renewed increase of tension should happen a little more often, and force another operative interference, it will be gladly accepted against the great advantage which the scleral flap gives against a late infection. The application of this principle finds difficulties in the thin buphthalmic wall, which, however, are not insurmountable. Such a flap formation of the sclera can be done after some experience in glaucoma of adults.

The vitreous prolapse could perhaps be evaded by replacing the trephining by a "scraping incision," as Professor Straub called it—an irregular cleavage of the sclera.

Some of the operated patients were shown; also two sisters suffering with buphthalmos, who had not yet been operated upon, who showed slow progress with good function; and an atrophy of the iris, which had progressed more in the older and seemed an ex-

ample of the aplasia of the iris, considered by Meller a causative factor in many cases of buphthalmos. However, in the younger child the same, but far less advanced change was found; and Zeeman believed that these are two stages of the same process, and that the iris atrophy is secondary.

Discussion.—Rochat asked why Zeeman had given up the sclerotomies of Snellen. He has a few patients, on whom he performs them from time to time, each half year, or year, a sclerotomy, and is very well satisfied.

Zeeman replied that the trials to make the trephining less dangerous had led Straub to a sort of sclerotomy, the favorable result of which was shown in one of the patients. In communications about sclerotomies after Snellen he had not found an inducement to perform this operation.

Visser inquired about the size of the trepans, and asked if many small openings would not minimize the danger connected with trephining.

Snellen corroborated the bad prognosis in older cases and considered operation indicated for younger ones. However, he points out the probability of spontaneous cure, and the impossibility to foretell this.

Zeeman considered Visser's proposition worth considering; and replied to Snellen that he had shown two children of 6 and 8 years as examples of a favorable course without operation. But such a course could not have been expected, as not only the large size of the cornea and the high pressure, but also marked symptoms of decompensation (opacities, epiphora, etc.), had constantly been present.

Dubois objected much to the repeated sclerotomies, as defended by Rochat. He also experienced therewith complications, and did two trephinings with great satisfaction.

Tresling states, that in van der Hoeve's clinic peripheral iridectomy is much valued, which is combined with the sclerotomy.

Zeeman also testified to the value of peripheral iridectomy, which had been done in all his demonstrated cases, altho it increased the danger of the operation somewhat.

Fixation for Objective Observation.

A. Verwey reminds us of the difficulty of looking at one point exactly, thru small motions of the eye and head, which are of different characters, have other sequences and must therefore be well distinguished. This is done most easily by a subjective method, described by Dodge in his excellent book "An Experimental Study of Visual Fixation." If one fixes a strongly illuminated triangle a short time to reproduce an after image, and if one then looks at a millimeter paper, it will be impossible to keep an angle of this after image on a distinct spot of the paper. Thru this "pseudonystagmus of fixation" great difficulties are encountered in the production of small after images.

The uncertainty of the fixation is clear and an objective method is necessary. The principal difficulty is to distinguish the head motions from those of the eye, or, more clearly stated, to find an objective measure for the unconscious deviations of the visual line, that is the determination of the size of the fixation field of the retina.

The cornea was looked at with Javal's ophthalmometer, when some calomel particles were on it. One can see the well known picture of the steps, and in front of it the calomel particles. As the distance between these two is 3.9 mm., a simultaneous sharp observation is impossible, so that even under the most favorable illumination it is difficult to observe a displacement of both points over one-fourth part off one step.

Verwey computed the influence of the sole eye turning, of the sole head-turning, and of the sole head displacement, as well on the rotation of the visual line, as on the displacement of the particle on the cornea, and on the parallax of this particle along the corneal image. The result was that equality of the parallax of all three sorts of motion corresponds with a rather similar size of the rotation of the visual line. On the contrary, an equal devia-

tion of the corneal point, with the three different sorts of motion, belongs to a very unequal size of this parallax, and also to very large differences in the rotation angle of the visual line. It follows, therefore, that the observation of the parallax gives a good indication for the knowledge of this rotation, and not the observation of the rotation of the corneal point.

One-fourth part of one step of Javal's picture is the minimum which can be observed, which corresponds to an angle of 17 minutes. These 17 seconds correspond with a rotation of the visual line over 540 seconds, 574 seconds, and 529 seconds. Verwey found for different people with exact fixation a parallax of ¼ to 1 step, so that a fixation nystagmus of 9 minutes to 36 minutes can be called physiologic. A photographic way of registration can refine this method, but only with complete sacrifice of the normal course of the motions and of the clinical usefulness.

The described method is also very useful for the objective observation of the movements of the visual line, while following a point in motion or following an unbroken line, or in counting points and stripes. The reflex for following a point in motion goes out from the periphery, not from the macula, according to experiments of Dodge. An interrupted movement seems only possible, when consciousness comes in play. Acording to Dodge "The real problems of psychologic optics are not so much connected with the mythical fixation point, as with the relation with each other of the surfaces with more or less distinct vision."

These conceptions have to be considered for all kinds of problems: For stereoscopic vision and the horizontal disparation, for determination of the blind spot and of scotoma, for positive induction and the irradiation, for the valuation of the localization of the retinal elements and the connection between tactile and visual space. The measuring could be of value perhaps for the practice with central scotomata, retrobulbar neuritis, and insular sclerosis.

Discussion.—Weve stated that the enlarged ophthalmoscopic picture in the upright image seems to be useful for such observation.

Rochat said, that the touching with the gaze, as is seen in fixation, also is observed during accommodation.

Verwey agreed, that the interrupted visual motions can well be observed with the ophthalmoscope, but that the instrumentarium for more exact investigation would become very complicated.

Photography of the Background of the Eye.

J. K. A. Wertheim Salomonson read a paper that will be published elsewhere.

Discussion.—Schoute asked about the normal reflexes of the eye and their disturbances. Wertheim Salomonson kept clear of these in the way first indicated by Gullstrand, by keeping clearly separated the illumination and the observation cones of light.

Wolff asked if a trial with color-photography had been made.

Wertheim Salomonson stated that this would necessitate a 40 times longer exposure and that this is not permissible.

Rochat described the method used by Hagen, where the illumination is secured thru the sclera, and which may be even simpler than the way just described.

The Smallest Differences of Direction Distinguishable with the Eye.

C. Otto Roelofs mentioned that Hering made a sharp distinction between the "resolving power" and the optical space sense. The first is determined by examination of the minimum separabile, the second by examination of the smallest differences of direction observable with the eye. Visual acuity and resolving power would mean the same. Roelofs had two objections, one of which he has published. (A. J. O., v. 1, p. 430.) He stated that the minimum separabile is a very vague conception and he considers it advisable to replace it by examination of the observation circle or the smallest observation breadth. The second objection relates to the comparison of

the visual acuity with the resolving power.

Roelofs wishes a sharp distinction between the examination for the smallest observation breadth, and that for the smallest observable difference in direction. It seems, however, very one sided to consider only the examination of the first, for the determination of the visual acuity. This alone does not determine the acuity of vision. Straub called visual acuity: The power to get acquainted with differences of direction thru the eye. Accepting this then the examination of the visual acuity involves: 1.—The examination of the observation circle and the smallest observation breadth; 2.—The examination of the optical space sense (better called direction sense).

Roelofs has investigated the optical direction sense. If two neighboring points are perceived, their direction does not coincide with the moment, when they are observed separately. It cannot be the smallest observable difference of direction, because the field between the two points is already observed in another direction from that of either point. Straub therefore considered that this smallest difference of direction was found, not when the two points are observed separately, but as soon as the points seen together impress one as a little bar. He proposed as the experimental object two squares, put together, that is, a bar twice as long as broad, as the most appropriate object for determination of the smallest observable difference of direction. The circumstances for such a determination must be as favorable as possible, and he doubted much if with such an object these were fulfilled.

He therefore used two sets of rods: (a) Bars of 1/2 mm., 2/3 mm., up to 9/10 mm. Here the relation of length to breadth decreases constantly and nears 1. (b) Rods of 1/2 mm., 1/3 mm., up to and with 1/9 mm. Here the relation of length to breadth constantly increases. The examination is done in a hall, 18 m. long with ordinary daylight with his emmetropic right eye. Someone else put up the cardboards, on which the rods were made with India ink. Approaching the test, the longest distance was sought at which he could recognize the bar as such, and could indicate its direction.

It appeared soon, that before sure recognition he could recognize with probability the direction of the rod. It seems that the observation of the bar depends on the recognition of difference between length and breadth. If the angles are measured under which the length and breadth of the rod are seen, then the difference of these angles gives under the given circumstances the just observable difference of direction. With "certainty" no mistakes were made, with "probability" the number of mistakes was about 5 per cent. A minimum for the length of the bar was found of about 80 seconds with great probability, or of about 110 seconds with certainty. A maximum for length of course does not exist. Length to breadth were in relation of 2 to 1 for the shortest rod recognizable as such. The smallest breadth which is found is 17 seconds; this, however, is not yet the minimum.

The smallest breadth of a long line drawn with India ink is 2.5 to 3 seconds. If the line is still thinner, then Roelofs sees nothing. The minimum requirements found for recognizing a rod as such with great probability are: Smallest length about 60; smallest breadth about 3, smallest difference between length and breadth about 12 seconds.

If now a rod 80 seconds long and 68 seconds broad is taken, it cannot be recognized. The explanation must be found in the difference between the true length and breadth, and the observed or apparent length. The demands for a rod to be used as an experimental object in the examination of the smallest difference observable in direction, must be that in the first place the apparent length and breadth bear the same proportion as the true length and breadth. This is not fulfilled when astigmatism exists, nor when the breadth of the rod is smaller than the diameter of the observation circle. This last one is for the em-

metropic eye about 50 seconds. All rods thinner will therefore be apparently too broad and thus unfit for this examination. The breadth of a rod influences the perception of the length. In general, the larger breadth with small rods will favor a more just appreciation of length, and also reversely a greater length will give a more just appreciation of breadth. The apparent length will be relatively too small in such a case. We may therefore expect the most accurate results by using the broader rods. More investigations were made with other objects; a cross, broken line, etc. The observation of the difference in direction depends on different factors, as the form of the object, the size of the observation circle. With objects smaller than the observation circle we will never be able to find out the smallest observable difference in direction. The light sense is undoubtedly of great influence.

According to Roelofs the examination of the visual acuity ought to be divided into an investigation of the smallest observable difference of direction. Snellen's letters and similar optotypes may satisfy clinically, they are certainly not satisfactory for physiologic investigation, and the more accurate following up of changes in some pathologic cases. The principal aim of this communication was to determine experimentally the best methods for such examination. (This paper also appeared separately in the Tydschr. v. Gen., June 15, 1918, with illustrations.)

Discussion.—Wertheim Salomonson would produce the results differently. The number of observations accidentally guessed right, probably is as large as the number of mistakes. He would put the number of right observations = 100 lessened by the double number of wrong data.

Waardenburg asked if optical illusion while looking at the rods can surmount the vertical dimension.

Roelofs accepts with pleasure Wertheim Salomonson's suggestion. Differences in vertical and horizontal position can have hardly any influence on his numbers; neither can optical illusion have disturbed them.

Wertheim Salomonson asked if observation of a long thin line with a breadth of 3 seconds, may be compared with other results, where other retinal parts come into play.

Roelofs did not consider this observation of very great importance, in this investigation.

CHICAGO OPHTHALMOLOGICAL SOCIETY.

Dr. Heman H. Brown, President, in the Chair.

Meeting of November 18th, 1918, postponed from October 21st, 1918, owing to the influenza epidemic.

Superficial Punctate Keratitis.

Dr. Michael Goldenburg presented a case of superficial punctate keratitis in a girl, unmarried, age 25, bookkeeper, who first came under his observation August 30th, 1916.

Previous personal history; has always been in perfect health except occasional symptoms of flatulency, and the eye trouble which started about six months ago. She does not know how this started, or what brought it on. She complained of pain in the eyes, sometimes very severe, photophobia, profuse lacrimation, and at times marked disturbance of vision so that she cannot work. Her vision at that time was right 15/50; left 15/80.

Upon examination we found slight circumcorneal injection, conjunctival sacs filled with tears, pupils equal and regular and react well to light and accommodation. With oblique illumination one could see many small grayish elevations about 1 or 2 mm. in diameter scattered over the cornea. With the Coddington lens we found, in addition to these little elevations, many small grayish dots of about the same size that were perfectly flush with the normal cornea. The epithelium thruout was intact, retained its luster and did not stain. At no time has there been a tendency for these dots or elevations to join others and form larger ones, as we sometimes see in bullous keratitis.

This case has now been under my observation for over two years. I have seen these little elevations which come

in crops, always attended with pain of more or less intensity, disappear in five to ten days, leaving behind these little grayish dots and in another five or ten days they in turn disappear, leaving no recognizable sign of their previous presence. The crops at times come before the previous ones have entirely cleared up. At times there may be so many present that one cannot count them, and again there may be only four or five visible; they may appear in one or both eyes and at times alternately. For the past year she has been able to tell a few days in advance when a new crop was about to appear.

The disturbance of vision is entirely dependent upon whether these dots or elevations are in the pupillary area and the amount of lacrimation present. It is my belief that the pain is due to the formation of these little elevations, by which I mean that a fluid or cellular infiltrate appears anterior to Bowman's membrane, forcing forward the superficial epithelium, thus producing traction upon the delicate nerve filaments or corneal end organs: for as soon as these elevations have reached the maximum height the pain ceases and only the sense of roughness remains.

Every clinical examination and laboratory test has been made by competent internists, radiologists, rhinologists and odontologists: and all have reported negative findings. Every form of treatment known or suggested has been tried, i. e., rest by atropin, bandaging, bichlorid, and atropin ointment, subconjunctival injections, dietetic starvation, deep intramuscular injection of cacodylat of sodium, etc., but still these crops come and go. It is interesting to report that for the first seven or ten days that a new form of treatment is resorted to she would show improvement, then she would drop back again. She has during all this time also been under the care of a thoroly competent internist.

Her vision with a small minus correction can be improved to 15/20 in either eye when the cornea is sufficiently clear.

My object in presenting this case is not its rarity, but its stubborn response to treatment, and in the hope that some one may cast some light on the apparent obscure etiology of this case and thus aid in its treatment.

Discussion.—Dr. Tydings asked if it took the fluorescein stain.

Dr. Goldenburg said no. In superficial punctate keratitis it never stained. In herpetic keratitis you will have some staining; that is a point of differentiation.

Dr. Tydings suggests that we eliminate every possible source, particularly sinuses or tonsils. The patient in case of sinus trouble may have blebs come on fingers or back of hands. Wherever you have septic conditons you will almost always find trouble in sinuses or tonsils.

Spontaneous Hemorrhage into the Vitreous.

Dr. H. W. Woodruff presented a case of spontaneous hemorrhage into the vitreous. The patient, G. V., age 20 years, came to the Illinois Charitable Eye and Ear Infirmary, April 28, 1918. He claimed to have lifted about 500 pounds and about two hours after was unable to see. Vision right eye, could count fingers at one foot; left eye, 15/200. Blood pressure systolic 110. Diastolic 80. Urine analysis negative. Wassermann negative. Tubercular test negative.

Treatment: Atropin in both eyes, pressure bandage. Internally, syrup ferric iodid, 30 min. three times a day. Hot applications. Referred to Nose and Throat Dept., tonsils were removed. Also given iodid of potash three times daily.

Discharged Aug. 25, 1918. Condition improved. Vision, right eye 20/30, left eye 20/100.

On November 2nd patient was admitted to the hospital stating that on October 25th he had lost the vision in the left eye almost immediately. No history of any strain. Vision, right eye 20/20. Left eye light perception.

Treatment: Hot applications. K. I. gr. 10. Atropin 1 per cent each t. i. d. November 18th, vision right eye 20/20, left eye 3/200.

Ophthalmoscopic examination shows extensive blood in the vitreous.

These cases are not so very rare. I have seen two of them in the past year. I had hoped that Dr. Faith would present his case of retinitis proliferans, as such a condition follows these hemorrhages.

The prognosis is not good on account of these recurrences and the consequent damage done to the vitreous.

I have just had another case at the Infirmary with a specific history. Retinitis proliferans in one eye and hemorrhage into the vitreous of the other eye. Had had so many salvarsan injections that we refrained from giving him antiluetic treatment. When these hemorrhages are repeated serious damage is the result.

Discussion.—Dr. Tydings.—Did this case fail to recover?

Dr. Woodruff.—He recovered vision in the eye with the recent hemorrhage. I refer to the last case mentioned with specific etiology.

Dr. Mundt.—What was the fundus like when discharged?

Dr. Woodruff.—Retinitis proliferans in one eye. No sign of hemorrhage except some vitreous opacities, but normal vision.

Dr. Goldenburg—Where do you suppose this hemorrhage came from? I believe many of them come from the ciliary vessels.

Dr. Woodruff.—I cannot say from what vessels the hemorrhage occurred.

Dr. H. H. Brown.—The case shown tonight by Dr. Woodruff is very interesting on account of the youth of the patient (20 years), and the lack of any history that would explain the etiology. There must be, however, some constitutional cause. Dr. Woodruff has made no statement as to family history. Was there anything in the family history?

Dr. Woodruff.—The family history was negative.

Dr. Goldenburg had a similar case in a woman apparently healthy, who originally presented herself with a unilateral neuroretinitis which eventually cleared up, although the etiology was never discovered and every test and examination had been resorted to. About six months later she suddenly appeared with the statement that she had lost her vision in that eye the night before. She was taking a bath when, without any warning, everything became dark before this eye. Upon examination nothing was to be seen externally, pupil dilated, reflexes both direct and consensual present, ophthalmoscopic examination was impossible as we could produce no red reflex. The diagnosis of a hemorrhage in the vitreous chamber was made, probably from the ciliary body. A consultant concurred in diagnosis, but not in prognosis. She responded to antiluetic treatment pushed to the limit; this treatment gave the best results for her neuroretinitis previously. Vision when last seen in this eye was 20/30 with some floaters in the vitreous.

Dr. Tydings.—I do not think that the etiology of her retinitis is dependent on any other factor than toxins. I have seen it in diabetes. There are many cases which could not be diagnosed. It might be either diabetes or T. B., and yet it is not dependent on any one factor. Any toxin might give rise to hemorrhage conditions in the retina.

Dr. Von Der Heydt.—In connection with these vague, spontaneous hemorrhages I have two possibilities in mind, not as yet mentioned in this discussion. One is hemophilia, for the exclusion of which a coagulation test can be made. If in a case, the hemorrhages are monocular, one must bear in mind the possibility of malignancy.

Dr. Woodruff.—We have spontaneous hemorrhages in the conjunctiva which are exceedingly common. So far there is no explanation for this. It occurs in people with apparently perfect health. It makes a great deal of difference where the hemorrhage is. These hemorrhages in the case of the young man are quite different from those cases where you have definite symptoms of syphilis. Might it not be that whether this hemorrhage came from the ciliary body or the choroid, might there not be some congenital malformation in these vessels? Quite a number of cases have been reported. They occur

over and over again thru a period of years.

Ophthalmoscopy with the Redfree Light of Vogt.

Dr. Robert Von der Heydt read a paper on this subject. See p. 122.

Discussion.—Dr. Brown.—It is useless to say that a paper such as the one presented entails an enormous amount of work, and I know that I am voicing the sentiments of the Society when I say that we owe a great deal to the author for presenting this very interesting subject. I know that the doctor needs encouragement in this work. Are there any suggestions or questions?

Dr. Woodruff.—I have enjoyed this paper very much and have long been hoping for a light that I have always thought of as an artificial daylight. Occasionally in examining a fundus I have been able to utilize sunlight, and it is quite a revelation. There is a very different appearance of the fundus by daylight. It is important in making differential diagnosis in conditions of the nerveheads. I expect to see the day when we may have an artificial daylight.

Dr. Noble thought the Society was to be felicitated on having a member who is taking up this work. It had occurred to him that it would be a proper thing for the officers of the Society to get behind Dr. Von der Heydt and in some way aid him in perfecting it.

Dr. Mundt.—The subject discussed by Dr. Von der Heydt is very interesting and it seems that when he has finished the work we will have a diagnostic method of great value.

Regarding the subject raised by Dr. Woodruff of the desire for an artificial daylight. For well over a year I have used my perimeter in my dark room which is illuminated by a Day-Light Nitrogen lamp known as a C2 Day-Light lamp. Under this light colors are the same as in daylight and it has the one great advantage of being a constant illuminant. This lamp was introduced to the medical profession by Peter.

Dr. Smith.—Has the doctor investigated if glass manufacturers know of any reason why chemical ingredients cannot be combined in glass, so that the trouble of having chambers containing the solutions would be eliminated?

Dr. Goldenburg.—An interesting phase would be the ability to trace the nerve fibers from the nervehead to the macula. I did not know these fibers ran beyond the macula. It would be exceedingly interesting in cases of retrobulbar neuritis.

Dr. Murray.—When I was inspecting a hospital in Pisa, Italy, in 1906, my attention was called to a small hole in the wall of the dark room, communicating with the outside. The doctor explained to me that it was their means of utilizing natural daylight for ophthalmoscopic examinations. The appearance of the fundus is certainly vastly different when using this source of illumination from what we are accustomed to, and it is easy to conceive that our ideas regarding fundus findings in general may be greatly changed when such a light as Dr. Von der Heydt describes has been adapted to practical use.

Dr. Von der Heydt.—(In closing.) Dr. Goldenburg has anticipated my next paper regarding optic neuritis. In cases of retrobulbar neuritis Vogt finds that the macula papillary bundles have disappeared. Regarding Dr. Wood ruff's remarks pertaining to ophthalmoscopy by sunlight, this would be ideal for diagnosing optic nerve atrophy, as its qualities would be almost constant. With artificial light we may use one light now, and then another. Not alone may our sources of light vary in yellow, nerve heads in themselves are different—deep cuppings and plainly visible laminae cribrosa, also different degrees of capillary vascularization and tissue deposits, cause various degrees of white to yellowish normal discs. Again the lenses in our own eyes change as we grow older. Fifteen and twenty years ago a nervehead appeared whiter to us than it would today. The diagnosis of slight pallor of the disc will always remain a personal equation.

In answer to Dr. Smith, a glass cannot be constructed containing these chemical ingredients or it would have been made over there. They have been experimenting for years. The subject is quite complex. I have prepared all summer in order to be able to present this matter tonight.

ALFRED N. MURRAY, M. D.,
Secretary.

COLORADO OPHTHALMOLOGICAL SOCIETY.

DECEMBER 21, 1918

DR. C. E. WALKER, PRESIDING

October and November meetings were omitted on account of influenza epidemic.

Traumatic Staphyloma of Sclera.

H. R. STILWILL, DENVER, presented an Italian coal miner aged 23 years who, on stumbling in the dark, had fallen forward on his face, striking the right eye against the hard rubber handle of an electric machine. When seen two days later, there was hemorrhage in the anterior chamber, with crescentic bulging of the sclera above in the ciliary region. The cornea was intact, and the upper part of the iris had disappeared beneath the bulging sclera, the appearance being practically that of an iridectomy except that there were no angles to the pupil. The conjunctiva was not ruptured but was chemotic. The eyeball was soft and vision equal to light perception.

In a few days the fundus could be seen through the lens, which was not dislocated. The bulging of the sclera now measured 4 by 8 mm., with about 2 or 3 mm. of elevation. The bulging was dark blue in color, probably due to thinning of the sclera with the ciliary body and anterior portion of the choroid lying beneath. Vision with —2.00 sphere was 4/12. A moderate return of pain and redness of the eyeball, a few days previously, with slight tenderness to pressure, had been readily controlled by atropin and dionin.

DISCUSSION. Melville Black, Denver. It is interesting to speculate whether the large opening in the sclera will undergo cicatrization and closure. This eye might be regarded as an eye dangerous to its fellow. Should operative procedures be instituted, or should future developments be awaited? It is difficult to know whether to open the eyeball and suture, or to await the slow disintegration that is likely to occur, with probable ultimate removal of the eyeball. The eye is not likely to recover much usefulness as a visual organ.

Edward Jackson, Denver. The case reminds me of cases of simple extraction with prolapse of the iris. In only one of my cases was the prolapse excised; and none of the cases gave any trouble. The condition in this case is probably somewhat more dangerous than prolapse after cataract extraction; but if the vision does not go down more the danger of sympathetic inflammation is probably small.

C. A. Ringle, Greeley, believed that such cases did better if left alone.

Otis Orendorf, Canon City, had seen a case similar to this one, in which the injury was also due to a fall. There was no conjunctival wound but a scleral bulging about the size of this one, with severe reaction. The eye was retained for three or four years, but the staphyloma became so disfiguring, being also accompanied by pain, that the patient, a young woman, asked to have the eye enucleated.

E. T. Boyd, Denver, believed from the position of the wound and the engagement of the iris that there would be a chronic uveal irritation which would result in phthisis bulbi.

George F. Libby, Denver, would advise expectant treatment.

H. R. Stilwill (closing). So far as the condition of the retina of this eye was concerned the man would probably have very good vision. Like Dr. Libby, he believed the eye should be watched. If it were his own eye he would hold on to it for a while.

Thromboses of Central Retinal Vessels.

H. R. STILWILL, Denver, presented a woman aged 57 years, who had consulted him on October 24th, 1918. In the previous August she had noticed a "cloud" which came suddenly before the right eye, and since that time had been able to see very little with the eye. There was no history of injury or inflammation.

The general health had always been good, and her physician had reported a blood pressure of 135 mm. of mercury, the urine negative and no indication of arteriosclerosis or cardiac disease. The ophthalmoscopic examination showed the entire fundus dotted with hemorrhagic patches. The nerve head was not swollen, but was in large part covered by exudate. The *veins* were dilated and tortuous and in places covered with extravasated blood. Those of the arteries which could be seen were extremely small and thread-like.

William H. Crisp, Denver, reported the case of a man 32 years, who had come in an hour and a half after becoming suddenly blind in the left eye. The patient was tuberculous, and was living in a tent. He stated that he had had a similar attack two months previously, lasting only a half hour, and followed by perfect recovery of vision. When he first came in the fundus of the right eye presented the very characteristic appearance of so-called embolism of the *central retinal artery*. The vessels were thread-like, there was a puffy pallor of the general fundus, and a cherry-red circular patch at the macula. This macular patch had later given place to an irregular brown spot. There had been no recovery of vision. The lesion in this case seemed likely a thrombosis. The heart was apparently normal.

Discussion. George F. Libby, Denver, recalled a case of venous thrombosis which he had presented to the society some years previously. In this case the eye disturbances complicated a nephritis which was apparently due to a fourth of July drinking bout. This was 18 years ago and there had been no ocular or general disturbance since.

Melville Black, Denver. Dr. Stilwill's case was a beautifully typical one of what was formerly called apoplexy of the retina. These cases should not be confused with the arterial cases.

Edward Jackson, Denver, believed that he had not seen quite so many venous as arterial cases; and he had seen more venous cases involving branches than of the central vein.

Orbital Periostitis and Abscess from Trauma.

John A. McCaw, Denver, presented a boy, aged 15 years, who two years previously had been thrown from a truck, striking his nose and left eye on the cobblestones. Two weeks ago a swelling had appeared over the left eye, about midway between the internal and external canthi and a little below the upper rim of the orbit. The swelling, which was tender to touch, had varied somewhat in size, but at the time of showing the patient there was a distinct increase in volume, and fluctation could be detected. The upper margin of the orbit was tender. (Puncture of the swelling, with a hollow needle, after the date of the meeting, revealed the presence of pus, and of a disturbance of the periosteum.)

Discussion. Melville Black, Denver, suggested that it would be simple and advantageous to introduce a hypodermic needle into the swelling and aspirate some of the contents. If the condition was an inflammatory one the mass should be opened and drained. If it was a lacrimal tumor it might subside of its own accord.

W. C. Bane, Denver, described a case of multiple swellings below the right external ear and in the throat of a boy of 13 years, with involvement of the cervical glands, and subsequent appearance of a nodular mass near the outer canthus of the right eye. Examination of a gland from the neck disclosed a large-round-cell sarcoma.

H. R. Stilwill, Denver, thought that the growth in Dr. McCaw's case would probably be hard if it were malignant.

Edward Jackson, Denver, thought that there was some thickening of the periosteum around the swelling. He thought it likely that the bone was diseased as a result of the injury, even tho the swelling was not due to trouble in the frontal sinus.

Nodular Opacities of Cornea.

John A. McCaw, Denver, presented a woman aged 43 years, who had come to the clinic six weeks previously complaining of fairly recent loss of vision in the left eye. The history was negative and there was nothing to point to syphi-

lis. There was no inflammatory reaction in the eye. The examination of the cornea with the corneal microscope revealed fifteen or twenty fine white spots in the substantia propria.

Discussion. Edward Jackson, Denver. There had at no time been any appearance of inflammation in the eye, either superficially or deeply. Under magnification, the spots had very much the appearance of the usual spots on Descemet's membrane. They were probably well forward in the substance of the cornea. The case seemed more or less of the character of nodular keratitis or nodular opacity, such as came on rather well along in life. There were no lines such as would give it the character of grill-like keratitis. The condition was more probably tuberculous than syphilitic in origin.

Optic Neuritis.

Melville Black, Denver, presented a man, aged 29 years, a barber by trade, who four weeks previously had gone suddenly blind in the left eye. The history was negative as to injury or infection. A Wassermann test was positive 4. There was a rather typical choked disc, without noticeable hemorrhages.

W. C. Bane, Denver, presented a married woman of 54 years, the vision of whose left eye had become dim one week before she was first seen on November 25th. The vision of the affected eye was reduced to 5-30ths. There had been dull pain behind this eye and a feeling of heaviness in it, and the eye appeared to project slightly beyond its fellow, altho the exophthalmometer revealed less than a millimeter of exophthalmos. The right fundus was normal. The left disc was moderately swollen and its edges indistinct. The vision of the left eye on November 27th was of the hand as an object, and on November 30th almost nil. The swelling of the disc gradually increased, reaching three diopters by December 2nd, on which date there were some linear hemorrhages, and the pain about the eye was so severe as to interfere with sleep. The urinary test and x-ray examination of the sinuses were negative. On December 12th six teeth, found to be diseased, were extracted, considerable hemorrhage following. On December 16th the pain was very much diminished and the swelling of the disc decidedly reduced. On December 21st the swelling of the disc was almost gone but the vision was nil.

George F. Libby, Denver, reported a case of binocular optic neuritis in a woman of about 40 years, apparently due to alveolar focal infection associated with nasal blocking. The patient had stated that on May 25th, 1918, there was sudden loss of vision in each eye, the right quickly recovering its sight but not the left. Dr. J. R. Arneill found the physical examinations negative. Treatment of indicanuria and a two months' rest were followed by restoration of normal vision. Then occurred an acute rhinitis, when vision dropped nearly to the low point of two months previously. With subsidence of the rhinitis the vision again became normal. Soon after this a devitalized tooth containing a bit of broken dental instrument was extracted upon Dr. Melville Black's advice, and streptococcus was found in culture. X-ray pictures of this and seven other devitalized teeth showed no suspicion of alveolar blind abscess. Dr. T. J. Gallaher found a deflection of the nasal septum to the left, with pressure contact. Dr. Libby, to whom the case was referred for ophthalmic examination on September 10th, found the disc margins obscure and the nerve heads hyperemic and slightly swollen. Vision R. was 5-5ths mostly, L. 5-5th partly. A submucous resection of the nasal septum was done by Dr. Gallaher on September 11th. On October 4th the disc margins were sharper and the hyperemia gone. The vision was 5-3rds mostly in each eye, but asthenopia still persisted, although not a previously noted scotoma. On October 19th the seven devitalized teeth were extracted and two of them showed streptococcus viridans abscesses. On December 6, 1918, the nerve heads were normal, although, like those of the patient's son and mother, not so well defined as the average disc; and the vision was still 5-3rds mostly, with tolerance of close work.

Discussion. Melville Black, Denver, thought that the blindness or almost ab-

solute blindness in the first two cases, out of proportion to the amount of swelling of the discs, suggested that the cause for obstruction of the circulation was well forward; as contrasted with cases of bilateral choking of the discs from cerebral gumma, in which the reduction of vision was often slight. In the case reported by Dr. Libby, he had unsuccessfully advised the extraction of teeth on account of the finding of streptococcus viridans in the one previously extracted.

George F. Libby, Denver, referring to an impression that Dr. Bane thought the benefit from the extraction of the teeth perhaps largely due to the bleeding, said he believed that a purely depletive benefit from bleeding was temporary, and that permanent benefit meant removal of toxins. He felt that his own case was probably one of toxic neuritis.

Edward Jackson, Denver, referred to a case recently reported in which the eye was entirely blind, and it was suggested that the nose should be operated upon. But this action was delayed, and in a few days the other eye went blind, and both eyes subsequently developed complete optic atrophy. Dr. Jackson felt that in the case referred to the patient might not have had the misfortune to become blind in both eyes if the nose had been freely opened up. Dr. Libby's patient might have had a very thin or dehiscent wall, so that congestion in the sinus would soon involve the optic nerve.

Corneal and Uveal Tuberculosis.

W. C. Bane, Denver, presented a colored woman, aged 28 years, in the lower third of the cornea of whose right eye were four "mutton fat" deposits, varying from one-third to one-half mm. in diameter. There was a similar deposit in the lower angle of the anterior chamber, and the whole cornea was moderately steamy. On November, 1919, the vision of this eye was fingers at 15 inches, that of the other 5-5ths. There was slight circumcorneal injection, the pupil measured 4 mm. in diameter and was inactive, and the tension of the eye was 28 mm. of mercury. No view of the fundus was obtainable. There was no history of tuberculosis, but the patient had come to Colorado 15 months previously and had lost weight since doing so. The Wassermann test and the complement fixation test for tuberculosis were both negative. Instillation of atropin rather rapidly produced acute glaucomatous pain and tension with complete loss of vision, and, in spite of partial relief from the use of eserin and acetylsalicylic acid the tension had remained about 52 mm. of mercury. Within the past ten days one mg. of T. R. had produced a positive reaction, and a rise in temperature to 100 degrees F. in the afternoon, but no local reaction. The high frequency current had proved soothing to the eye.

Discussion. Edward Jackson, Denver, had seen rises of intraocular tension in connection with other cases of tuberculosis uveitis. From a somewhat limited experience of such cases he would say that there was a decided tendency in this direction. An operation in this case should not be hastily undertaken. If the original process subsided the tension was also likely to come down. The fact that there was no focal reaction rather suggested a focus of tuberculosis elsewhere.

Dr. Bane doubted the wisdom of any operative measures in the case, in the presence of probable tuberculosis.

C. E. Walker, Denver, had operated in the presence of tuberculous conditions and had seen no difference in the healing process after such operations, as compared with other cases. If no result was being obtained in bringing down the tension of the eye, he would certainly consider an iridectomy. He had done an iridectomy in several eyes which he believed to be tuberculous.

Melville Black, Denver, objected to doing either an iridectomy or a trephining in such case on account of the risk of hemorrhage.

Puncture Wounds of Crystalline Lens.

E. T. Boyd, Denver, presented two patients, each of whom had suffered a penetrating injury involving the cornea, iris, and lens. A youth of 19 years was struck in the left eye by a dressmaker's pin thrown by another youth from a distance of about ten feet. The cornea was penetrated a little outside the pupillary margin in the lower outer quadrant, the

pin passing also thru the iris into the lens. When the patient was seen one hour after the injury, the anterior chamber was full of soft lens matter and the iris was in contact with the wound. The use of atropin relieved the synechia in about two days, the lens matter was rapidly absorbed, and the eye became quiet. A man of 29 years who was driving an ax on to its handle was struck in the right eye with a splinter of wood from the timber on which he was pounding; the injury affecting the cornea, iris, and lens in much the same way and location as in the first case; and in this case also the anterior chamber was rapidly filled with soft lens matter and the iris was adherent to the wound. Here again, the synechia was relieved by the use of atropin, and, at the time of the demonstration, the lens substance was steadily being absorbed and the eye becoming quiet.

Traumatic Conical Cornea.

William H. Crisp, Denver, presented a boy, aged 12 years who, on the 11th of December had been struck on the left eye by an unknown foreign body while driving a wagon. The only two suggestions obtainable as to the source of the blow on the eye were first that something might have exploded in an ash wagon which was approaching at the time, and second that some boys not far off might have fired a toy rifle. The blow was a very severe one, and the boy was in a mild condition of shock when he came to the office one hour and a half after the injury. The epithelium of the lower inner fourth of the left cornea was much lacerated, and there was a central circular area of complete stripping of the epithelium, suggesting that the foreign body, whatever its character, might have come from the left, struck the center of the cornea and then glanced along the cornea toward the nasal side. The morning after the injury it was noticeable that the whole depth of the cornea between the nasal side and a little to this side of the centre was bulging considerably in the form of a flattened cone. There was a severe general reaction. As healing developed, the only staining was along two irregular lines roughly at right angles with one another, extending across the bulging area. No other part of the eye showed traces of the injury. Vision of this eye was 5-60ths, and no attempt had so far been made to find a correcting lens. The tension of the eye was slightly subnormal.

Discussion.—W. C. Bane, Denver, and C. E. Walker, Denver, suggested the use of a pressure bandage to reduce the bulging.

Edward Jackson, Denver, thought a pressure bandage would not do any particular good, but would tend toward softening of the tissues if it were worn for some time. He had seen a case treated with a compress for months do better after the compression was left off. After the inflammatory reaction had subsided, pilocarpin or eserin might be of some advantage.

Otis M. Orendorff, Canon City, referred to a case in which there had been apparent softening from the use of a compression bandage, and furthermore the patient would not wear the bandage on account of pain.

Dr. Crisp believed that, on account of the spherical shape of the eyeball and the hydrostatic distribution of any pressure applied to it, and further in view of the fact that it was impossible to insure a fixed position of the eyeball under the bandage, such a bandage could produce no benefit and might be harmful by producing an effect exactly opposite to that desired.

Dr. Walker argued that if a compress were used both eyes should be treated in the same way, so that motion of the eyeball would be restricted.

Postdiphtheric Paralysis.

James J. Pattee, Pueblo, reported a case of postdiphtheric paralysis in a woman of 36 years. Antitoxin had been used. The paralyses developed a little over two weeks after the onset of the diphtheria, which had continued for about ten days. There was weakness of the limbs, and definite paralysis of the soft palate and of the intrinsic muscles of the eyes. The vision improved much more rapidly than the throat condition, and she still complained of inability to force food down the lower part of the esophagus.

Discussion. Edward Jackson, Denver, had personally experienced complete paralysis of accommodation after diphtheria. Recovery was complete within six weeks. Throat paralysis was noticeable as soon as the soreness of the throat was over, and it was two years before he could swallow fluids with complete certainty and confidence, and six months before he entirely overcame the paralysis involving the limbs.

William H. Crisp, M. D., Secretary.

ABSTRACTS

Roy, J. N., Vision among the Blacks of Africa. Ann. d'Ocul., 1918, v. 155, p. 513.

Roy examined about 5,000 negroes belonging to 22 different colonies, from an anatomic, physiologic and pathologic standpoint. He has observed that in the same individual, the vision was better in the tropics than in the temperate zones; so that normal vision in the tropics should be regarded as 7/5, rather than 5/5 or even 6/5. The Africans of the coast, especially the northern and northeastern sections, have come in contact with other races, especially the Arabs and Egyptians, and have suffered from diseases acquired thru this contact, such as variola, purulent ophthalmia, trachoma, and syphilis. From this it results that the Africans of the North show eye diseases much more frequently than those of the South, the latter having contracted them from those of the North.

The abundance of pigment in the eyes of the negro is very striking; sometimes the choroid, iris and ocular conjunctiva, especially near the outer canthus, seem to be almost saturated with it. Some negroes also show physiologic melanosis of the velum palati and gums.

The refraction is almost always emmetropic, except where pathologic changes have altered the corneal curvautre. Myopia is found in 1.5 per cent of the population and always of very low degree; never more than 4. D., and then in albinos. Albinism is very common, but it was not found that albinos intermarry. There was about the same percentage of myopic astigmatism, while hyperopia and hyperopic astigmatism were found each in about 2.5 per cent of cases, but never of a high degree. Compound astigmatism was occasionally found, especially in albinos, but never mixed or irregular astigmatism, except, of course, as the result of keratitis. The refractive errors are somewhat more numerous in the regions where schools have been established for a long time for educating the negroes.

When either the convex or concave glasses were required, a vision of 9/5 to 11/5 was often obtained. The best vision obtained in an emmetrope was 20/5, in a patient with "sleeping sickness." The average visual acuity of negro emmetropes is 12/5. They are able, when diving, to see at great depths. Changes in color sense and hemianopsias are never seen. Experiments showed the negroes see at night two to four times better than do the whites, probably due to the former's more frequently being in the dark. No anatomic basis so far as preponderance of rods, such as is found in night animals, was observed.

An interesting table is given of 50 observations, on negroes of various tribes between 13 and 30 years of age, dealing with the vision and the accommodation. The latter was anywhere from 1 D. to 3 D. greater than at the corresponding age in the white race. It would seem that with the development of the brain in the higher races goes a corresponding deterioration of the sense organs, especially those of sight and hearing, due probably to the manner of life, use of artificial lights, inherited diatheses, alimentation, study, prolonged use of the eye, etc.

C. L.

Moreau, F., Disturbances of Macular Vision Caused by Traumatic Lesions of the Occipital Region.—Ann. d'Ocul., 1918, v. 155, p. 357.

Since vision consists not only in recognition of the existence of a point or line, but also in determining its movements, distance, depth, etc., these factors should be investigated in hemianopsia as well as the determination of the losses in the field. That is, in the ordinary visual fields there are zones of orientation, distinction, and precision, in passing from the periphery to the center. By the use of a stereoscope with Haitz' or Joseph's charts these zones can be determined. Different letters of the same size are used, instead of points or squares, and the places where these are recognized are joined into a zone of "distinction." The examination must be frequently interrupted to avoid the antagonism of the visual field. The central vision is tested by means of Holmes' or Pigeon's stereoscope provided with special test objects, consisting of 6-rayed stars, either white on black background, or black on a white background. If the largest is seen complete, the area of central vision is normal. If branches or part of the nucleus is obscured, smaller ones are tried until one is found which is seen complete. Three case reports with interesting representations of the visual fields are given.

General Results of Visual Troubles in Hemianopsia with Central Lesion. (a) Reading.—There is an irregular rythm of reading by hemianopes different from the uncertainty of the amblyope. It is more difficult for them to read writing than printing, and unfamiliar than familiar texts. (b) Writing.—On unruled paper, the right hemianope has much more trouble than the left. On ruled the difference is not so great. In the former, the lines slant downward.

HEAT IN THE TREATMENT OF CORNEAL ULCERS.

From the first use of the actual cautery in the treatment of wounds down to the days of Pasteur and aseptic surgery, heat has been a reliable means of destroying infection. Increased knowledge of pathology and the recognition of pathogenic organisms have enabled us to apply it more exactly and effectively. But from the time when the cautery was first used to check suppuration, the problem has been to do this completely with the least damage to the invaded tissue.

Since Martinache described his use of the actual cautery to check the progress of a corneal ulcer over 45 years ago, many instruments for such application of heat to the cornea have been employed, from the steel knitting needle held in an alcohol flame, or the copper ball to hold the heat with a projecting point to touch the ulcer, to the numerous forms of galvanic cautery tip mounted on handles of varied weight and convenience.

In 1892, Lippincott reported his favorable experience in the use of hot water dropped on certain corneal ulcers. He advised heating the water to 160° F., or over, and dropping it directly on the ulcerated surface.

In 1899, Bourgeois called attention to the sterilization of corneal ulcers by blowing hot air upon them. He used a bent metal tube attached to a rubber bulb, similar to those used by dentists to dry cavities preparatory to filling. The tube is held in the flame of an alcohol lamp and the air drawn back and forth in the tube three or four times and then immediately expelled against the surface of the ulcer, which at once becomes white. The process can be repeated as often as necessary.

Eleven years later he reported, that depending wholly on this method for the sterilization of infected corneal ulcers, his results were truly remarkable. Rozet reported a similarly favorable experience with the method; but it seems not to have been widely practiced. The cauterization by live steam which has been used in the frontal sinus by Dennis, seems not to have been tried for corneal ulcers. Boiling alco-

hol and other fluids that might furnish a perfectly definite temperature are also untried.

In 1910 Weekers published his method of applying heat to the cornea by holding the cautery point as close as possible to the ulcer without actually touching it. He first used an olive shaped cautery, in the manner afterwards described by Prince under the name of Pasteurization. But Weekers soon substituted the galvanocautery tip as the source of heat, pointing out that the temperature required for sterilization was about 65° C, or 150° F.; and that the needed color and proximity of the cautery tip to develop and sustain such a heat could be readily learned by holding the tip close to the bulb of a mercurial thermometer.

Lastly Shahan worked out his thermophore by which the metal tip, heated to a known required temperature, could be held in contact with the surface of the ulcer for the necessary time, one minute; making the application of heat more exact than had heretofore been possible.

To check a corneal infection it is not necessary to boil or char the organisms. It is only essential to raise them to such a temperature as will destroy their power of multiplication; and the temperature that will effect this is one that will not in the required time do any great damage to the cornea itself. The most important service that Weekers has rendered in this matter is his experimental showing of how little damage need be done to corneal tissue, by heat that will sterilize the pathogenic organisms. (See p. 90.)

The final determination of the best means of applying the desirable degree of heat, must await a considerable experience with the different methods on the part of the profession in general. The hot air method of Bourgeois is extremely simple and easily applied and repeated. But on account of the greater penetrating power of radiant heat, the methods of Shahan, and Bourgeois seem more likely to reach and render innocuous the more deeply seated organisms.

The treatment of corneal infections by heat will become more exact and its results more satisfactory in proportion as it is carried on with a clear understanding of exactly how much heat is needed and how much is being applied.

E. J.

THE RADICAL CURE OF DACRYOCYSTITIS.

Chronic lacrimal sac disease is the *bete noir* of the Ophthalmic Surgeon, provided that he goes not at its cure by radical removal of the apparatus,—the last resort and to which nearly all cases should come.

True it is, that a certain proportion seem to recover after the nasal disease, particularly concomitant sinus affections, have been elmininated; and a few are cured by drainage with injections.

We have our choice of several radical methods of obliterating the sac:

1. The rhinolacrimal method of West and modifications, the intranasal operation; a somewhat difficult procedure largely advocated by the rhinologists.

2. Obliteration of the sac by caustics, recently resurrected by Gifford, who claims good and quick results from trichloracetic acid. The writer's small experience with nitric acid in the old days and with trichloracetic acid recently, has been that it is painful, causing edema and slow healing with prolonged after treatment.

3. Excision of the sac, preferably after the method of Meller, under local anesthesia by novocainadrenalin, when made by a master is one of the prettiest of all operations, and one in which the writer's experience gives full satisfaction.

Compensatory lessened secretion of mucous and lacrimal fluids certainly obtains after obliteration of the lacrimal canals; so that, except upon exposure to irritants as dust or smoke or winds that would make any eyes water, such patients do not generally complain of tearing, and in fact obtain relief from their watery eyes.

H. V. W.

BOOK NOTICES.

Transactions of the Ophthalmological Society of the United Kingdom, Vol. 38, 384 pp., 56 ill., 9 pl. London, J. and A. Churchill, 1918.

The striking characteristic of this volume as compared with its predecessors in the series are well set forth in the Presidential Address of E. Treacher Collins in these words:

"You will have noticed that this volume has, like so many of us as an outcome of the war, had to tighten its belt. It is considerably reduced in bulk, due to the thinness of the paper. I am, however, pleased to say it is only superfluous matter with which it has had to dispense, the number of its pages and the amount of interest in its material being well up to the average."

An evidence of the "tightening of the belt," which is to be regretted, is the absence of any colored plates such as have added much to the value of former volumes. But in the number, interest, and importance of the papers presented, this volume is one of the best that this great society has published. As in former years, the papers are grouped under their appropriate heads as "Diseases of the Cornea," "Diseases of the Uveal Tract," etc. There are two symposia, each including several important papers, one on "Contagious Diseases of the Conjunctiva," the other on "Plastic Operations of the Eyelids."

However, despite its accustomed appearance, this volume marks a change in the life of the society of tremendous importance to it, and to ophthalmologists thruout the world. On its title page appear after "Transactions of the Ophthalmological Society of the United Kingdom," these added words, "With which are affiliated the Egyptian Ophthalmological Society, Midland Ophthalmological Society, North of England Ophthalmological Society, Oxford Ophthalmological Congress." And in the appendices are included five papers read before the Oxford Ophthalmological Congress and three from the Midland Ophthalmological Society.

This reaching out to coördinate the scientific work of the ophthalmologists of the British Empire is directly in the line of progress; and for an organization whose members reside in every quarter of the globe, cannot fail to react strongly and favorably on the life of the parent organization. It is significant that among the visitors contributing to these transactions are some well known American ophthalmic writers and workers. To have place in such a volume may well be regarded as an honor; and these men have thoroly deserved it.

More than ever should these transactions be generally found in the libraries of all English reading ophthalmologists. There is no literature relating to ophthalmology of greater permanent value.

E. J.

The Surgery of Oral Diseases and Malformations; Their Diagnosis and Treatment. George van Ingen Brown, D. D. S., M. D., C. M., F. A. C. S. Third edition. 734 pages, with 570 engravings and 20 plates, and a selected list of examination questions. Lea and Febiger, Philadelphia and New York, 1918. Price $7.00.

This book contains more than indicated by the title, as it is not only a complete treatise on oral diseases, but also a work of reference touching all medical interests in their oral relations. Thus the first chaper presents an excellent discourse on anesthesia and anesthetics, general and local, their methods of administration and their dangers; on hemorrhage and its treatment; and on shock. Other chapters deal with infection, fever, tetanus, tuberculosis, syphilis, etc., considering in detail diagnostic methods and treatment, diseases of the nervous system affecting the buccal region, nasal deformities and diseases in relation to the maxillae, diseases of the maxillary sinus, of the bone, glands, tumors, etc.

The special subjects are discussed in the sections on diseases of the mucous membrane of the mouth, and on hare-

lip, cleft palate, and defects of speech. These represent the chief part of the author's life work, and their discussion is based upon his extended experience in that line. All important pathologic conditions affecting, or influenced by, the buccal cavity and its immediate surroundings are entered upon, and the operative procedures are clearly described. A great portion of the illustrations are original and representations of the author's cases.

The most important change in this new edition is the chapter on war surgery in which the author gathered representative ideas and methods published from the work of the hospitals of practically all the principal belligerent nations.

The subject matter is very well systematized, and orientation is greatly facilitated by the use of heavy type for the headings of the different paragraphs. From the broadness of conception in which this valuable book is written, it will be read with great interest and benefit by every physician.

C. Z.

BIOGRAPHIC SKETCHES

T. H. Shastid, M. D.

SUPERIOR, WISCONSIN.

Frederick Eustace Batten was a well known London ophthalmologist, especially renowned for his researches in familial diseases of the eye. Born at Plymouth, England, in 1866, third son of the late John Winterbotham Batten, K. C., he received his training in the liberal arts at Westminster and at Trinity College, Cambridge; and his medical education at St. Bartholomew's Hospital, London. He was a member of the Council of the Ophthalmological Society of the United Kingdom from 1904-'06 and Secretary from 1906-'09. His death occurred suddenly on July 27, 1918.

John Couper.—A celebrated London ophthalmologist, specially renowned as diagnostician and teacher, was born at Glasgow, Scotland, Nov. 7, 1835, son of John and Charlotte Tennant Couper. He received the M. D. at Glasgow in 1856, and the F. R. C. S., England (exam.), in 1861. Settling down in London, he was, for a time, assistant surgeon and demonstrator of anatomy at the London Hospital. From 1869 to 1889 he was surgeon in the same institution, as well as lecturer on surgery. He was also, for a number of years, surgeon, afterwards consulting surgeon to the Royal London Ophthalmic Hospital and to the Scottish Hospital. He was a Fellow of the Hunterian and Harveian Societies. Among his more

John Couper, 1838-1918

important contributions are: "The Diagnosis of Astigmatism by the Ophthalmoscope" (B. M. A. Newcastle, 1890); and "A New Magazine Ophthalmoscope" (Trans. Oph. Soc. of U. K., 1883).

Celebrated ophthalmologist as he was, Dr. Couper at no time in his life wholly gave up general surgery.

In 1868 Dr. Couper married Helen Campbell, of Otter, Argyllshire, with whom he would have celebrated his golden wedding in Oct., 1918, had not his death intervened. He died at Falmouth, England, April 30, 1918.

Regarding the personality of Dr. Couper, a friend has written in a private letter as follows: "John Couper loved his work, and the only distinction he aimed at was to do his very best in it. Those who have learned from him, and worked with him, say he was 'a born teacher'—'a fine general surgeon' as well as 'a singularly able and intelligent eye surgeon.' With 'a remarkably clear, sound mind,' he was 'simple and transparent,' absolutely unassuming, and keen to learn as well as to teach. He had a warm appreciation of other men's good work, and rejoiced in their successes and distinctions. By patients and friends he was greatly loved and respected and regretted."

The following appreciation from the pen of Sir Anderson Critchett appears in "The British Journal of Ophthalmology," Vol. II, No. 7, at p. 396: "Ophthalmoscopic work always had a great attraction for Couper, especially the estimation of errors of refraction by the direct method—retinoscopy was then unknown—and in his desire for increased power of dealing with the minutiae of such cases he armed himself with specially constructed ophthalmoscopes which contained numerous lenses. His most favorite implement finally took the shape and proportions of a carpenter's rule which, following the custom of that workman, he usually carried in his trousers pocket.

"As he was unable to emulate the example of Sir Boyle Roche's famous bird and to be in two places at one and the same time, it naturally followed that as soon as he considered his senior clinicals to be capable of dealing with the routine of the outpatients' department he entrusted them with a large share of that work. My colleagues and I took full advantage of these golden opportunities, tho we sometimes had to drag our reluctant chief from the dark room when some new case involving special knowledge and experience proved too responsible for us to essay.

"Couper was one of the first to recognize and to point out the excellent results which often followed the correction of very slight refractive errors, especially in cases of astigmatism; and he calmly pursued his way in that direction without heeding the gentle ridicule which Donders was at that time inclined to cast upon it. He made frequent use of atropin in refraction cases, and he preferred to give the full correction for myopia. I believe I am right in stating that he continued to the end to work with Paris inches; and his special box of lenses contained glasses worked in weird and complicated fractions, which would have been a terror to anybody but himself.

"Couper was an exceptionally good operator, possessing full command of very dextrous hands, and his only fault was a tendency to linger too long over the toilet of the eye after cataract extraction. In these days of cocain this might perhaps be accounted a virtue; but when anesthetics were almost always administered, the habit occasionally resulted in serious disadvantage. Like Noyes, of New York, he preferred an extremely narrow Graefe knife; and, unlike Swanzy, he made a large iridectomy."

The following, from Sir John Tweedy, appears at p. 399 of the same number of the same journal: "Altho a good surgeon and a skilled operator, his qualities were those of an ophthalmic *physician. Facile princeps* among the ophthalmoscopists of the day, he was one of the first in this country seriously and scientifically to study problems of the errors of refraction, and especially of astigmatism. His diagnostic skill and his careful method of investigation attracted a body of thoughtful pupils, not a few of whom afterwards attained to notable distinction. . . .

"His mental temperament was essentially skeptical. Not unbelief; not misbelief; but hardness of belief was his intellectual attitude to all surgical and scientific questions. He did not believe easily or lightly, but only when convinced by the force of reason and by the potency of well observed facts. This skepticism may not have been an unmixed benefit as a teacher to beginners, but it was a real advantage at a hospital like Moorfields, where many

of the pupils, assistants, and visitors were actual or potential experts. . . .

"Couper was indeed a lovable man, a true friend, a staunch and loyal colleague. To have known him and to have been so long associated with him is an abiding satisfaction, and the recollection of a friendship unclouded thruout many years is a precious possession."

Carl Calvin Culver was a well known ophthalmologist and otolaryngologist of Burlington, Kansas. Born in Woodson County, Kans., July 5, 1887, he received the medical degree in 1911 at the University of Kansas Medical School. On July 5, 1911, he married Miss Pearl Muender, and then settled as ophthalmologist and otolaryngologist in Burlington, where he practiced until his death. He joined the army service in August, 1917, with the rank of lieutenant, and died in camp, Oct. 8, 1918.

Charles Huff Davis. This well known ophthalmologist and otolaryngologist was born at Lebanon, Va., Aug. 25, 1875, son of Mr. and Mrs. John Lynch Davis. His training in the arts and sciences was received at the University of Tennessee. For a time he was a reporter on "The Knoxville Sentinel." Turning his attention to medicine, he received the medical degree at the Lincoln Memorial University, Knoxville, Tenn., in 1898.

He at once proceeded to study the eye, ear, nose and throat in Chicago, where he was appointed senior interne in the Illinois Charitable Eye and Ear Infirmary. But shortly afterward he returned to Knoxville, where he practiced as ophthalmologist and otolaryngologist. He was specialist for the Southern and the Louisville and Nashville railways, and for the Aluminum Company of America, at Marysville, and for The American Zinc Company of Tennessee, at Mascot. He was a Fellow of the American Medical Association, the American College of Surgeons, the American Laryngological Society, and a number of similar bodies.

Dr. Davis married, on June 25, 1900, Hortense Burton. There were no children. He was a man of high moral character and a skillful ophthalmologist. Of medium height and build, he wore no beard, had a very dark complexion, bright hazel eyes, and dark brown hair sprinkled with gray. He was gay and brisk in manner, very genial, a lover of animals, a patriotic citizen, a Mason, a member of the Methodist church.

Dr. Davis died at his home, 1404 Laurel avenue, on Oct. 21, 1918, from pneumonia following influenza.

J. Flemming. This famous Berlin ophthalmologist was widely known for his experiments on trachoma corpuscles and on the therapeutic action of radium and mesothorium. Born in 1874, the son of a preacher, he became a student in the Kaiser-Wilhelm Academy. Having received his medical degree, he soon was troop physician, later physician in chief to the "Plöner Cadet Institution." Promoted to the aerial service, he made a large number of experiments in aviation, and, in this way, was of great service to the German Government. He also thoroly studied the aerial bacteria, of which he named large numbers. From 1907-'11 he was assistant to Professor Greeff. He died of a wound in a field hospital, in his forty-fourth year.

Charles W. Haddock. A well known ophthalmologist of Beverly, Mass. Was born in Beverly, June 3, 1856, son of the late Dr. and Mrs. Charles H. Haddock. After a preliminary course of study at the Massachusetts College of Pharmacy, he attended the Harvard Medical School, where he graduated with the class of 1879. From 1880-'82 he studied at Heidelberg and Vienna, and, returning to America, practiced at Beverly with his father until the latter's death.

Then he studied the eye, ear, nose, and throat in Boston, Philadelphia, and New York; and, beginning with 1892, devoted himself for nineteen years exclusively to ophthalmology and otolaryngology at Salem and Beverly. Mass. In 1915 he retired from practice. He died Dec. 14, 1918, after a long period of ill health, survived by a widow and one son, Charles C. Had-

dock, who is in the Research Department of the Army at Washington.

Frederick Carroll Heath. A prominent ophthalmologist of Indianapolis, Ind., was born at Gardiner, Me., Jan. 19, 1857, son of Alvan M. C. and Sarah Hinckley Philbrook Heath. He received the A. B. at Amherst in 1878, the A. M. in 1886, and the M. D. at the Maine Medical College (Bowdoin) in 1884. Shortly afterward he studied the eye, ear, nose and throat, and settled in Indianapolis as a specialist on the diseases of these organs.

Dr. Heath was assistant surgeon in the U. S. Marine Hospital Service for six years, Secretary of the Indiana State Medical Society for fourteen years, eye surgeon to the Indianapolis City Hospital and Dispensary, to The German Lutheran Orphan Asylum, and The Eleanor Hospital; also professor of ophthalmology at the Indiana University Medical College from 1905 until his death.

Dr. Heath married, on June 19, 1895, Agnes Ralston Cochrane, of Indianapolis, by whom he had one dauhter, Mary. The Doctor died on Oct. 16, 1918, survived by his widow and daughter.

Isaac H. Lent. This Middletown, N. Y., ophthalmologist, of considerable local reputation, was born on a farm in the Mohawk Valley in 1846. He received in 1873 his degree in medicine at the Albany, N. Y., Medical College. For fifteen years he practiced general medicine at Valatie, N. Y., and then studied the eye, ear, nose and throat in New York and Philadelphia. Settling at Middletown, N. Y., he practiced there for the rest of his life. For a number of years he was consulting ophthalmologist to the Thrall Hospital, Middletown. His death occurred from spinal hemorrhage about Oct. 20, 1918.

Roy Richard Longino. This prominent Texas specialist on the eye, ear, nose and throat, born Dec. 17, 1888, son of Stephen Beasley and Edna Young Longino, received the medical degree at Tulane University, New Orleans, in 1911. On June 5, 1912, he married Ruth Bransford, by whom he had one child, Mary Ruth. During the year 1913 he was assistant superintendent to the State Epileptic Asylum, Abilene, Texas. Later, he practiced as ophthalmologist and otolaryngologist at Ft. Stockton.

He was a man of impressive appearance, large, strong, somewhat stout, smoothfaced and fair complexioned. He was deliberate in manner, but full of quiet energy, and very devoted to his profession. He was an Elk, a Mason, a Methodist. A friend of the Doctor writes "Perhaps no man, for his age, was more respected and loved in any community. Especially the children and the old people will greatly miss him." He died at his home, Oct. 18, 1918, from influenza and its complications.

Joseph Williams Lovibond, author of numerous works on color and the inventor of the tintometer, was born in England in 1833 and died there April, 1918. He joined the rush of gold seekers to California in 1849 but soon returned to England and became manager of a brewery. He wrote books on "Light and Color Measurements," "Color Phenomenon," and "Color Theories," and many papers with regard to color. The tintometer, a color scale for comparison, has been widely used in the arts and for blood testing.

Charles Emery Payne. An oculist and aurist of Brooklyn, N. Y. Born in Camden, Me., in 1882, he received the medical degree in 1903 at the New York Homeopathic Medical College. For fourteen years he practiced in Brooklyn. He was consulting laryngologist and rhinologist to the Jamaica and Cumberland St. Hospitals, attending physician to the Home for Consumptives, a member of the Advisory Board to the Peck Memorial Hospital, and laryngologist, rhinologist, and assistant oculist and aurist, to the Brooklyn Nursery and Infants' Hospital. He died at his home, on Nov. 18, 1918, from pneumonia.

Thomas Tounge Perkins was an eye, ear, nose and throat specialist of Cliftondale, Mass. Born in Auburn, Me., he later resided in West Durham, Me., and Lynn, Mass. He was a grad-

uate of the Massachusetts Institute of Technology, of the Boston University, and, in medicine, of the Harvard Medical School, in 1901. He seems to have settled, soon after his graduation in medicine, at Cliftondale, and to have practiced there continuously. In his later years he became an ophthalmologist and otolaryngologist, as well as an expert with the microscope. He was a Universalist, a Royal Arch Mason. He died Dec. 6, 1918, from heart disease.

George Rupp Pretz, a well known ophthalmologist and otolaryngologist of Lebanon, Penna., was born at Steelton, Penna. He graduated at the Steelton High School, Gettysburg College, and, in 1909, at the Johns Hopkins University, Medical Department.

He settled, at first as general practitioner, in Lebanon; but later decided to limit his practice to the eye, ear, nose and throat. He was ophthalmologist and otolaryngologist to the Good Samaritan Hospital at Lebanon, and a Fellow of the A. M. A. He was also a prominent Mason, and an active worker in the Seventh Street Lutheran Church.

At the very beginning of America's entry into the war, he tendered his services to the War Department, was commissioned a lieutenant; and shortly afterward was called for duty at Camp Greenleaf. On Sept. 4, 1918, he wrote to a friend in Lebanon, "This is a great life. I'm in the best of health." On Sept. 20, however, he died, from pneumonia, the result of influenza.

Michael Philip Schuster was a prominent ophthalmologist and otolaryngologist of El Paso, Texas, and founder of the Providence Hospital in that city. Born in Gyor, Hungary, in 1860, he received his medical degree in 1889 at the University of Vienna, Austria. For the next three years he was chief assistant to Prof. Fuchs.

Coming to America, Dr. Schuster settled in Kansas City, where, for a time, he was chief surgeon to the American Smelting and Refining Co. He also taught for a number of years in the Kansas City College of Medicine.

Removing to El Paso, Texas, the Doctor remained chief surgeon to the American Smelting and Refining Co., a position which he held, all told, for eighteen years. In 1905 he was President of the El Paso County Medical Society. He was also a Fellow of the American College of Surgeons and a thirty-third degree Mason.

Dr. Schuster died at his home on Nov. 15, 1918, after a year or more of illness. He was survived by two daughters, and by two sons—Dr. Stephen Schuster, commander of Base Hospital 129, Camp Shelby, Hattiesburg, Miss., and Dr. Frank P. Schuster, Medical Reserve Corps, Cook County Hospital, Chicago.

Halstead Robert Wright, 1875-1918

Homer Warren Thompson was an ophthalmologist and otolaryngologist of Salem, Ohio, well known locally. Born at Salem, Dec. 8, 1859, son of Joseph Warren and Hannah Ann Thompson, he received the medical de-

gree at Pulte Medical College, Cincinnati, in 1885. He married, on April 12, 1900, Miss Cora May Owen. He was a well known aeronaut. His death occurred from angina pectoris, Feb. 8, 1918.

Halstead Robert Wright. A young American ophthalmologist of great promise. Born at Coshocton, Ohio, May 20, 1875, he removed to Columbus with his father's family in 1880. He graduated in dentistry at the University of Ohio in 1895, but after a brief period of dental practice, took up the study of medicine in the same university, where he received the medical degree in 1910.

He then located for practice in Columbus, becoming a partner with his father. He was, from 1910 till 1917, instructor in physiology and pathology at his alma mater. He invented a number of ophthalmic instruments, and contributed to "The Ophthalmic Record" a number of ophthalmic articles, among which may be mentioned the following: "The Use of the Snare as the Final Step in the Enucleation of the Eye"; "A New Method of Preparing an Eye for Microscopic Sections"; "A Rare Intraocular Tumor," and "A Rare Tubercular Condition of the Eye."

Dr. Wright was a large, robust man, smooth faced, of fair complexion, with dark brown eyes and hair. He was very serious in manner as a rule, but enjoyed an occasional joke. He was very fond of fishing. He was a Democrat, a believer in Christianity, but not a member of any church, a thirty-second degree Mason, and a Shriner. He became a captain in the Medical Service of the Army, and died at Camp Greenleaf, Georgia, Oct. 17, 1918, survived by his father, also by his wife and son.

Charles O. Zahner. An ophthalmologist and otolaryngologist of Louisville, Ky. Born in 1880, he received the medical degree in 1904 at the University of Louisville. He was also a graduate of the Louisville College of Pharmacy. He died of influenza at his home, on Oct. 11, 1918, survived by his widow, Blanche McCleary Zahner.

NEWS ITEMS

Personals and items of interest should be sent to Dr. Melville Black, 424 Metropolitan Building, Denver, Colorado. They should be sent in by the 25th of the month. The following gentlemen have consented to supply the news from their respective sections: Dr. Edmond E. Blaauw, Buffalo; Dr. H. Alexander Brown, San Francisco; Dr. V. A. Chapman, Milwaukee, Dr. Robert Fagin, Memphis; Dr. M. Feingold, New Orleans; Dr. Wm. F. Hardy, St. Louis; Dr. Geo. F. Keiper, LaFayette, Indiana; Dr. Geo. H. Kress, Los Angeles; Dr. W. H. Lowell, Boston; Dr. Pacheco Luna, Guatemala City, Central America; Dr. Wm. R. Murray, Minneapolis; Dr. Edward F. Parker, Charleston, S. C.; Dr. G. Oram Ring, Philadelphia; Dr. Chas. P. Small, Chicago; Dr. John E. Virden, New York City. Volunteers are needed in other localities.

DEATHS.

Claude Huston Case, Kansas City, Kansas, aged 44, died from pneumonia following influenza, October 22nd.

George A. Cubbison, Erie, Pa., aged 55, died at his home, December 21st, from pneumonia following influenza.

N. C. Macnamara, of Hertfordshire, England, died November 21st, 1918, at the age of 86.

Mitchell Mikkelsen, Wells, Minn., aged 68, died at his home from pneumonia, January 8th.

Samuel L. Oren, Lieut., M. C., U. S. A., Lewistown, Illinois, aged 39, who after a course of training at Fort Oglethorpe, Georgia, was sent overseas, died in France, October 9th, from nervous collapse presumably following ambulant typhoid fever.

Charles Henry Weintz, Captain, M. C., U. S. A., Cincinnati, aged 33, assistant chief of the nose and throat department of the base hospital, Camp Sherman, died at the Camp, October 14th, from pneumonia.

PERSONAL.

Major Vard H. Hulen, sends Christmas greetings from Bordeaux, France.

A son of Dr. H. H. Burnham, of Toronto, Canada, was killed in action in France.

Dr. John F. Rowland of Hot Springs, Arkansas, has been elected president of the Garland County Hot Springs Medical Society.

Dr. Robert H. Miller announces the removal of his offices to 711 Los Angeles Investment Building, Broadway and Eighth streets, Los Angeles, California.

King George of England has recently appointed Sir George Anderson Critchett, Surgeon Oculist in Ordinary to His Majesty; and Richard Robert Cruise, Surgeon Oculist Extraordinary.

MILITARY NOTES.

Captain Frank Brawley has been transferred from Mineola, L. I., to Millington, Tenn.

Captain C. P. Small has been assigned to duty at the government arsenal at Rock Island.

Captain J. W. Foley of Denver, Colorado, has been granted an honorable discharge from the army.

Captain F. C. Bakes of Albuquerque, New Mexico, has been granted an honorable discharge from the army.

Major George F. Suker has been transferred from Pittsburgh to the Walter Reed Hospital, Washington, D. C.

Captain G. T. Jordan has been transferred from Camp Grant to temporary duty in the Department Surgeon's office—Central Department, Chicago.

Major T. A. Woodruff has obtained his release from the service, and will reside at New London, Conn.

Dr. W. H. Roberts of Pasadena, who entered the service as a Captain, was recently promoted to the rank of Major, being stationed at Camp Lewis.

Dr. C. G. Stivers of Los Angeles, Captain in the Medical Reserve Corps, is in charge of Aviation examinations at San Francisco.

Major Burton Chance has been mustered out of service, and has resumed practice at 255 South 13th street, Philadelphia, Pennsylvania.

Captain F. L. Anderson, attached to Base Hospital, Camp Logan, has been honorably discharged and resumed his practice at Roswell, N. Mex.

Dr. George H. Kress of Los Angeles was Senior Surgeon in charge of the University of Southern California Students' Army Training Corps until the same was mustered out with the other S. A. T. C. organizations thruout the country.

Dr. William T. Shoemaker of Philadelphia has been appointed ophthalmologist to all the American hospitals in England. Dr. Shoemaker went to France in May, 1917, as ophthalmologist to the Pennsylvania Hospital unit. Two of his sons are in the service.

Major C. W. Kollock, who entered the Aviation Medical Service, U. S. A., has been discharged and is resuming his practice of ophthalmology and oto-laryngology, and his duties as Professor of Rhinology and Laryngology in the Medical College of South Carolina in Charleston, S. C.

On authority of the Office of the Surgeon General of the Army, it is said that there may be less than fifty American soldiers who suffered total blindness from wounds received in action. This is considered a remarkable record for the number of men engaged, and the intensity of the fighting in the sectors where Americans were engaged.

Sir C. Arthur Pearson, head of the British National Institute, which is devoted to the care of men who have lost their sight in the war, and himself blind, sailed for the United States and Canada, December 20th. The object of his visit is to confer with those responsible for the care of American soldiers blinded in the war and with Canadian authorities regarding the future welfare of Canadian soldiers trained at St. Dunstan's Hotel for Blinded Soldiers and Sailors, London.

When the war began Sir Arthur Pearson was president of the National Institute for the Blind in England. He organized the blind soldiers' and sailors' care committee and set about to find a suitable building where these men might be trained to be self-supporting. The selection was St. Dunstan's in Regent's park, London. Only sixteen men entered at first, but now there are close to 600 in training in the institution; 250 are in the hospital, and almost 700 trained men have left, some to take up their former work and others the new occupations they have mastered.

SOCIETIES.

The twelfth semi-annual session of the Sioux Valley Eye and Ear Academy was held in Sioux City, Iowa, on January 21st.

At a recent meeting of the Minnesota Academy of Ophthalmology and Oto-Laryngology, the following officers were elected for the ensuing year: President, J. D. Lewis of Minneapolis; vice-president, E. R. Bray of St. Paul; 2nd vice-president, A. D. McConnell of Minot, N. D.; secretary-treasurer, John Morse of Minneapolis.

The annual meeting and dinner of the Chicago Ophthalmological Society took place on January 20th, about sixty members being present. The guest of the occasion was Dr. Francis Park Lewis of Buffalo, whose address, "The Specialist, His Relation to the Profession and to the Community" was particularly apt at this time, and was enthusiastically received. One suggestion offered by Dr. Lewis which seems worthy of most thoughtful consideration is that the work of the Examining Boards, in co-operation with the Advisory Boards, by which the Government has been able to give the most skillful medical attention to our soldiers, be continued in practically the same method of operation, under federal supervision, for the benefit of the general civilian population.

The following officers of the Society were elected for the ensuing year: President, William A. Noble; vice-president, A. L. Adams of Jacksonville; secretary-treasurer, Alfred Murray was re-elected; councilor, Douglas Payne.

MISCELLANEOUS.

It has been calculated that the number of totally blinded victims of the war, among all the allied armies, is 7,000. Twenty-five or thirty per cent will probably have to be added to this figure from among the patients now undergoing treatment. The total of those who lost one eye amounts to between 30,000 and 40,000.

The quarterly report of the Illinois State Department of Public Welfare states that 2,000 blind adults are supported by county pensions in Illinois. Trachoma is declared to be the cause of the high rate of blindness in the southern part of the state.

In consequence of a world-wide shortage of spectacle lenses, frames and mountings, the War Service Committee of the Optical Industry, announces that the conservation policy adopted by the trade for the war will be continued during the reconstruction period.

As a result of the efforts made by the health authorities to eradicate trachoma from North Carolina, the State Board of Health has made this a reportable disease.

The fourth annual meeting of the National Committee for Prevention of Blindness was held in New York on November 26th. The speaker of the evening was Lieut.-Col. James Bordley who is directing the work for the blind in the Army and Navy, and is also director of the Red Cross Institute for the blind.

Mr. J. C. Gleason, who has been a music teacher in Chicago, but has been blind for twenty years, is lecturing in different parts of the country, assisted by local blind talent. He is acquainting people with the problems of re-education of the blind.

On the 22nd of November took place the ceremony of the first stone of the new Medical School of the University "Estrada Cabrera" of the Republic of Guatemala, on the same site where stood the old school that was destroyed by the earthquakes of the end of last year. The new buildings will be finished in 1921, first anniversary of independence.

The "Little Shop for the Permanent Blind Fund" in Chicago is meeting with most encouraging success. One needs to visit the shop to realize what beautiful pieces of work are being shown, most of which is the hand-work of young society women. Blanket covers made of voile and lace, boudoir and traveling caps, chiffon infant caps, negligees, washcloths and Red Cross dolls are among the articles that find ready purchasers. Everything in the shop is donated, and a number of the things are made by the wounded blind. A different committee of women are in the shop each day to take charge of the sales, the proceeds of which go to the permanent blind fund.

In the Red Cross institute for the blind offices are two blind girls, who four months ago answered an advertisement of the institute for stenographers. After four months' training they are said to be the equal of any stenographer in the city. They are being paid at the regular piece rates, and their earnings amount to from $18 to $22 a week.

The Bureau of Standards of the National Department of Commerce has prepared a tentative draft of a National Code for Head and Eye Protection which is ready for inspection and criticism. It is intended to perfect this Code so that it will be suitable for general application by industrial commissions and others having legal powers, as well as by private plants and casualty insurance companies who may wish to use it as their own standard. The Bureau will be glad to have oculists examine this at their earliest convenience and submit criticisms and suggestions for improvement in the requirements or the wording to Division I, Section 8, of the Bureau.

Extensive preparations for the swift education of blind soldiers so that they may go into the labor market on equal terms with workers who have their sight, have been completed by the Red Cross Institute for the Blind, working in conjunction with the office of the surgeon general of the United States.

Some idea of the scope of the work already completed may be gathered from the fact that a complete survey of every industry in the country has been made with a view to its applicability to blind workers. It has been found that more than a quarter of all United States industries can use the blind workers.

The methods of training have already been worked out by having the best workers in each industry do their tasks before a moving picture camera. The film is then "reviewed" by experts from the Society of Mechanical Engineers, who have donated their services to the government. These men eliminate all the waste motion in the processes and design instruments which will help the blind workman and increase his efficiency.

Already plans have been drawn by a large Eastern syndicate for a chain of "Victory stores" to be placed in all locations chosen by blind soldiers who wish to go into business. The syndicate, under the jurisdiction of the Red Cross will do all the buying for the storekeepers.

The December *News Letter* published by the National Committee for the Prevention of Blindness is most interesting reading. Ophthalmologists who would like to receive it regularly need only to so notify the Committee at 130 East Twenty-second Street, New York City. This committee is doing a work which should be known and supported by every ophthalmologist in the country. Their report on "Classes for Conservation of Vision" shows a gradual extension of such classes throughout the schools of our larger cities. It is a most valuable work and the School Boards of larger cities should have their attention called to it and be urged to found such classes.

OPHTHALMIC LITERATURE

These lists contain the titles of all papers bearing on Ophthalmology received within the preceeding month. These titles are all in English, some of them modified to indicate more clearly their subjects. These subjects are grouped under appropriate heads, the succession of groups being the same from month to month. In the group the papers are arranged alphabetically usually by the name of the author in heavy-face type. After the subject of the paper (Ill.) indicates the number of illustrations. (Pl.) the number of plates, and (Col. pl.) colored plates illustrating the article. (Abst.) shows that it is an abstract of the original article. (Bibl.) tells that the paper is accompanied by an important bibliography. (Dis.) means that a discussion of the subject is published with it. Under Repeated Titles are indicated additional publication of papers already noticed. To secure the earliest possible notice writers may send copies of their papers, or reprints, to 318 Majestic Bldg., Denver, Colorado.

INTRAOCULAR HEMORRHAGE IN BRIGHT'S DISEASE.
KERSHNER'S CASE.

AMERICAN JOURNAL OF OPHTHALMOLOGY

Vol. 2 MARCH, 1919 No. 3

OCULAR INTERNAL HEMORRHAGE IN A CASE OF BRIGHT'S DISEASE.

MAJOR W. E. KERSHNER, M. C., U. S. A.

BATH, MAINE.

This unique case history includes an ophthalmoscopic study of the pathology of certain well known lesions of the eye ground, here asssociated in an unusual manner, and clearing up with remarkable rapidity and completeness.

The case presented here is considered of sufficient interest to report for the following reasons: First—the changes are markedly different in the two eyes, the right showing a decided optic neuritis of the third degree, or to be more exact a neuroretinitis; the left demonstrating beautifully three types of retinal hemorrhage without neuritis. Second—the above changes occur in a young man who had no increase in blood pressure, no arteriosclerosis, and no increase in the white cell count. Third — elimination was at all tests proven normal or sufficient. The phenolphthalein test was used several times; albumin was present in the urine, and also casts, which were persistent. Fourth—the cause of extensive retinal hemorrhage, of whatever type, and neuroretinitis indicates in this case a common exciting and predisposing factor. Fifth—the sudden resolution with the simultaneous clearing up of the pathologic changes in both eyes points to a definite relation between the two conditions.

It is indeed interesting to watch the rapidly changing conditions in the left eye as they progressed, and as they retrogressed.

CASE.

The subject of this report came to the outpatient Eye Clinic of one of the Base Hospitals in the United States, on February 18th, 1918. At this time he complained that he could not see as well as usual, and that he had discomfort in his eyes. The patient was a tall, slim American of the brunette type, moderately well nourished, twenty-eight years of age; and above the average of his class and type in intelligence and strength of mind, as his personal history will show.

Family and Personal History.—Two brothers died of typhoid fever, one of diphtheria, and another in infancy. A sister died in infancy, another during labor. His wife died of puerperal eclampsia. This man is a mechanic in civil life, and works in cotton mills; the duties of his job are repairing looms. He denies absolutely any alcoholic indulgence for the past seven years; during the preceding four years, however, he drank heavily and constantly; he was intoxicated two or three times each week, and often drank 250 ccs. of whiskey before breakfast during these four years.

Previous Medical History.—Our patient had a series of attacks of objective vertigo about eight years ago, which improved after the discontinuance of cigarette smoking, to which he had been addicted for some years. Very slight manifestations of this complaint have visited him from time to time since the original attack, but have been controlled by diet and attention to his bowels. About six years ago he had

nocturia for a short period; this occurred once or twice each night. Measles and mumps fifteen years ago. Denies gonorrhoea and syphilis; also malaria, scarlet fever, smallpox, rheumatism and typhoid. There is no history of edema of the extremities at any time of his life.

The present condition dates only to February 14th, 1918, previous to which he had never had attention directed to his eyes. On this date the patient experienced a toothache-like pain in both eyeballs; the pain lasted longer in the left, and became quite severe. The vision begain to fail in both eyes, and as he expressed it, "There is a cloud over my eyes all the time." He, at the time, had slight dyspnea, after sharp drills, slight headaches, but slept well and relished his food. There were no gastric symptoms, no cough, nor night sweats. There was a slight increase in the postnasal discharge.

Ocular Examination.—Inspection negative, conjunctiva normal, ocular excursions satisfactory in all directions, pupils 2 to 3 mm., react to light, accommodation and convergence promptly; anterior ocular segments of both eyes normal.

Ophthalmoscopic Examination.—Right. Media clear; periphery of the fundus was congested with large tortuous veins; the arteries appeared full but not tortuous. The macula was heavily stippled and injected, as was the whole fundus; disc margins obscured, physiologic cup filled with exudate; perivascular lymph vessels full and bulging. The refraction of the nerve head was plus 1.5 D. We found here a clear picture of optic neuritis of the third stage, with a very few minute hemorrhages along the vessels.

Left. Media clear. Periphery of the fundus normal, except for the heavy tortuous veins; macula dark in color and heavily stippled. The nerve head was partly filled with blood to the nasal side above and below; there was no blood to the temporal side, nor was there bulging of the nerve head; no full perivascular lymph vessels. Extending from the disc, and appearing to come from in the disc, and reaching to the nasal side, was a roll-like hemorrhage, somewhat clubshaped, enlarging as it went from the disc, which formed an abrupt rounded end, 2½ disc diameters from the disc. The nasal end showed three distinct major rolls or folds, and several smaller ones; the rolls extended into the eye 1 mm., 1½ mm., and 2 mm., respectively. The color of this mass was uniformly deeper than the fundus, except for three irregular grayish white areas where the folds merged into one another. The whole fundus was only slightly, if at all, congested, altho the veins were large and tortuous.

The vision at this time was: Right = 10/200. Left = 20/40.

The examination the following day showed no change in the right eye except a slight increase in the number of small paravessel hemorrhages. In the left eye we found all that was seen on the previous day, with an additional hemorrhage of the subhyaloid type, extending from the disc up, one disc diameter. This mass was elongated, being 2½ disc diameters in the horizontal meridian. It covered the superior retinal vessel, and presented a sharply defined superior border and ends, but the inferior border seemed to blend with the hemorrhage in the disc, or to be attached thereto. This new hemorrhage was heavier in color and more coarsely stippled than the first one. The vision remained the same in each eye.

At the visit on February 21st, the right eye was found to be as already described, with the addition of more edema of the macula, and the development of the typical stellate exudate about the macula. The left again showed additional changes; there were present well defined flame shaped hemorrhages down from the disc between the inferior temporal and nasal veins which all but obscured the arteries. This extended dowward nearly one disc diameter. There were also the same type of changes above and at irregular intervals all around the subhyaloid mass. The base of these new areas seemed to come from beneath the margin of the second hemorrhage, both above and to the nasal and temporal

ends as well. Smaller flames were present above and below the original roll-shaped mass. These last additions to our study increased in extent and density somewhat for two or three days, by which time an illdefined stellate grayish exudate appeared surrounding the macula which was more pronounced above than below. The vision, now under homatropin was: Right = 1/200. Left = 20/200.

The writer does not wish to convey the impression that the original hemorrhage in the left eye has been absolutely as seen the first day. While in the main it has remained so, yet from day to day the width of some of the rolls has changed slightly and the position of this mass varied somewhat; that is, higher and lower on different days. The accompanying illustration indicates the process when fully developed. See Plate V.

This condition of affairs lasted seven days with little or no change in either eye. On the morning of the eighth day there was no change in the right eye, but in the left all efforts to outline the fundus except in the extreme periphery were futile. A grayish haze, indefinite and indistinct, was all that could be seen of the disc. The fundus reflex was very pale; the central portion of the fundus was even less distinct than looking at an object thru a dense fog; only a suggestion of the fundus reflex could be obtained. This, mind you, was March 3rd, 1918, at which time the vision was: Right = 3/200. Left, hand movement at 1/2 M.

The following morning, much to our surprise, the neuritis of the right eye was decidedly improved; in the left eye the fundus was visible, with an absolutely normal disc, with an entire absence of all hemorrhages except the subhyaloid above the disc. The only indication remaining of trouble in this eye was a slightly hazy deepening of color at the site of the original hemorrhage. The tortuous veins in both eyes were gone. Vision: Right = 20/200. Left = 20/30.

An additional twenty-four hours presented us with normal fundi and with normal vessels; except for the subhyaloid mass, in the left eye, which was little if any more than half its original size. The stippling was coarser in this area and grayish white spots appeared over the surface, which had a tendency to coalesce. As indicated above, the right fundus was now normal, except for a slightly striated fullness of the disc.

By the end of the third week the right eye presented a clear disc; normal fundus and vessels. In the left, continued contraction in the subhyaloid mass. Vision was now: Right = 20/30 plus 1. Left = 20/30 minus 1.

On March 18th, just one month after coming to the clinic, the vision was: Right = 20/20 minus 1. Left = 20/20 minus 2; with normal right fundus, and the left normal but for the hemorrhage, which now was about one-half its former size.

The form fields showed nothing unusual and coincided with like fields in any case of optic neuritis, namely, decided contractions for form and colors. In the left eye the form fields were not contracted to any marked extent, but there were absolute scotomata corresponding to the fringes or ends of the flame-shaped area. With the sudden resolution or release of neuritis in the right eye there was not a correspondingly rapid widening of the form field. The first day of the decided change for the better, the fields were practically not altered; the following day about five degrees widening manifested itself, and then proceeded a slow but steady increase in the width until it was about 10 to 12 degrees under normal, when the patient was lost to us.

The physical examination by the medical service is as follows: "The patient is a fairly well nourished and well muscled individual, with no deformities. Station and gait are normal, tendon reflexes are equal and normally active. Hearing to rough test is normal; the tongue is moist, clean, tooth-marked, and coarsely tremulous. The tonsils are well atrophied and very slightly cryptic. The superficial glands are not palpable, the thyroid is slightly palpable and visible. The peripheral vessels are palpable, but do not pulsate. The chest is asymetrical, on the

nipple level; the left side measuring 17¾ inches, the right side 16 inches. Expansion is shallow, but apparently equal. The lungs are resonant to normal limits, and expand at the bases. The breath sounds are vesicular; there are no rales."

"The cardiac impulse is neither visible nor palpable. The left border of the heart is 9 cm. from the midsternal line, and the right 2 cm. The cardiac rythm is normal, 96 to the minute while standing. There is a mild sinus arythmia; at the apex there is a short, untransmitted, systolic murmur with a well accentuated second sound. At the aortic cartilage the sounds are somewhat distant with a slight ring of the second sound. At the pulmonary cartilage the first sound is lost, but the second is clear. At all areas the sounds are somewhat distant. The systolic blood pressure is 124 mm. mercury; the diastolic 90 mm. In a recumbent position the cardiac rate is 72 per minute. After an effort test there is a perfect recovery in two minutes."

"No tenderness or rigidity in the abdomen is found. The liver is just palpable on deep inspiration. The kidneys and spleen are not palpable; the skin reflexes are active."

The laboratory findings were as follows: "No leucocytosis, no malaria, no hookworm, and negative Wassermann.

Examination of the urine, 24 hour specimens showed it always acid and free from sugar.

Date	Amount	Albumin	Microscopic
2/18	2200 cc.	Present	Red blood cells, hyalin and granular casts.
2/21	2200 cc.	Present	Granular casts.
2/25	2200 cc.	Trace	Granular casts.
2/27	1800 cc.	Absent	Few granular casts.
3/10	1700 cc.	Absent	Few granular casts.

There are manifestly conditions here which are of interest. These are a close relation between neuritis and ocular hemorrhages in kidney disease, or an anatomic factor in this left eye which manifested itself by an optic neuritis in the right; and hemorrhages, multiple and massive, in the left.

THE TREATMENT OF TRACHOMA AND CHRONIC CONJUNCTIVITIS WITH NEGATIVE PRESSURE.

B. M. Howley, M. D.

NEW BRUNSWICK, N. J.

This is the account of a practical method of treating trachoma less painful and less formidable than rolling the lids or grattage, but apparently capable of achieving similar results.

It is now three years since I began this treatment and my results have been so satisfactory that I feel that I am justified in reporting them. In the earlier stages of trachoma, when squeezing is the favorite method of treatment, this still ranks high in my estimation as the best method. But negative pressure at the time of operation or later can be of great service. It is to those cases of trachoma which are not operative cases, but which are so chronic in character, that they are almost incurable, that I wish to direct attention.

The most favorite method of treatment has been blue stone, and I must say that I think it is one of the most barbaric treatments that could be devised. The pathologists state that in trachoma there is a round cell infiltration with the formation of scar tissue, and at the same time they speak of an infection that has not been positively identified. Now, I will not enter into the pathologic or bacteriologic aspect of the disease, but I would like to draw attention to the fact that negative pressure is the most positive way of abstracting the secretion and infection from the conjunctiva of the lid.

Blue stone acts by its irritating qualities and abstracts water from the tissues. Negative pressure draws the se-

cretion and the infection from the glands and causes resolution to a certain extent in the affected lid. The amount of negative pressure that the patient will allow will vary, but I have had a negative pressure of ten pounds on the upper lid and five or six pounds on the lower lid. This is not a steady pressure, as you will be guided by the sensitiveness of your patient as you sweep your applicator across the lid ready to lessen the vacuum if it becomes painful. The junction of the upper lid with the culdesac, and the culdesac, are more sensitive to negative pressure, but with perseverance you will accomplish a great deal. The lower lid, altho sensitive, will stand

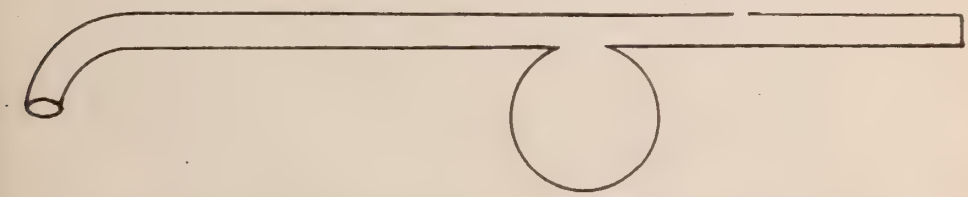

Fig. 1. Glass tube applicator of Howley. Curved tip to be applied to the conjunctiva; globe to receive secretion below, and opening in tube above by which vacuum can be controlled with tip of finger.

three or four pounds of negative pressure if you use the sweeping motions as I have advised in the upper lid. Be careful and do not pull the applicator from the tissues as it is painful and may tear the tissues. As a rule the average patient will bear six or seven pounds on the upper lid and three or four pounds on the lower lid without complaining.

At the beginning of this treatment I had a gauge which showed the amount of negative pressure, but later discarded it as I found it cumbersome and not of practical utility. The glass tubes used by me have been made by the Sorensen Pump Company, of New York, whose pump I use in my work, altho any good pump will do. They are modelled after tubes that have been made and used in nose and throat work. It is not necessary to have a vacuum gauge, as with your finger resting on the opening of the applicator you can regulate the amount of negative pressure according as your tube shows the entrance of secretion and the sensitiveness of your patient. If it is a case for scarification or scraping you will cocainize and then after scraping or scarification you will apply the negative pressure. Scraping with the aid of a small scalpel I think is one of the best ways of attacking the fine granular type of trachoma. In sensitive patients you may apply a four per cent solution of cocain to the lids, but the average person will let you treat them without it.

The conjunctiva of the upper and lower lids, also the culdesac, is cleansed with a solution of boric acid or bichlorid of mercury 1—10,000. After everting the upper lid I place the applicator on the lid and with a sweeping motion run the applicator over the conjunctival surface from the inner to the outer canthus or vice versa. Many sweeping applications can be made to the lid in this way until the tube shows secretion with some blood, if the surface is irregular or granular, and you may be amazed at the amount of secretion that comes from the lids.

The glass attachments are 120 mm. in length with a curved end 4x3 mm. that is applied to the tissues. There is a central bulb or chamber to hold the secretions that are drawn off, and 5 mm. back of the bulb is a small opening in the tube for the finger of the manipulator to make or break a vacuum as he desires.

If the trachoma is slow to yield I scarify and then use suction. Previous to scarification I wash the lids, especially the culdesac, with a solution of boric acid, and wipe with a solution of bichlorid of mercury 1-5,000. Cocain having been applied, I use a small scal-

pel or scarifier and scarify freely, wiping the blood away. I then apply negative pressure and remove the blood and infective material.

The patients who have thickened lids, and a conjunctiva of a rough, granular type, you cannot only scarify, but you can scrape with a small scalpel and then apply the suction tube. These patients, as in all cases that I have treated by this method, will invariably tell you that the eye feels better with the first treatment. In trachoma or in chronic conjunctivitis especially when it is monocular, it is always advisable to see that there is no stenosis in the nasal duct.

My results have been obtained in private practice and therefore, I have not a great number to report. I have had about twenty-five cases of trachoma, and they have varied from the mild cases to the most aggravated or severe ones. The mild cases yielded to negative pressure and if slow, a moderate scarification followed by suction yielded quick results. In these cases negative pressure is applied two or three times a week, followed by an application of bichlorid of mercury 1-5000, or argyrol 20 per cent. Scarification could be performed every two or three weeks as indicated by the progress of the case or the severity of the disease. Silver nitrat 1 per cent or 2 per cent is of great benefit in these cases. For home treatment I order hydrargyi bichlorid 1-10,000, argyrol 20 per cent, or zinc sulphat gr. 1 to 1 oz. Persistent treatment along these lines will cure some cases in three months.

The severe cases that have been progressing for years are not so amenable to treatment, owing to the marked infiltration in tissues and the formation of new connective tissues and its resulting deformity. In these cases I always begin as soon as possible with a scarification, which I make as thoro as possible, and then apply suction to the bleeding tissues. My results have been good and very satisfactory, but not as satisfactory as in the milder cases. This is due to the pathologic changes and formation of new tissue. The results have been better than from any method I know of, excepting certain cases where tarsal removal may be performed. It seems to me that the early application of negative pressure, with scarification in these thickened lids, will make tarsal removal unnecessary.

In your old trachoma cases you will clear up an infective discharge, make the eye feel much better and reduce your infiltration to a great extent, but you cannot remove connective tissue by this method.

Chronic conjunctivitis that resists treatment by the ordinary methods will speedily yield to negative pressure with local applications. Vaccines have been made from the infection obtained from the conjunctiva with negative results. Whatever is the primary cause of trachoma—the latter stages show a mixed infection.

In conclusion I wish to say that in trachoma there is no remedy in my hands that has been as beneficial as negative pressure, as it removes the infection and causes absorption to take place in the infiltrated tissue.

DETACHING OF BULBAR CONJUNCTIVA AS A TREATMENT OF TRACHOMATOUS PANNUS.

Kazuo Hiwatari, M. D.

KYOTO, JAPAN.

This method evolved from modifications of tarsectomy has something in common with the old operation of peritomy for pannus, and yields very favorable results as here reported.

There are various kinds of treatment of trachomatous pannus, among which friction with certain medicaments, cauterisation, peritomy with some modifications (Agnew's operation or Denig's transplantation, for instance), and tarsectomy are to be mentioned.

The indication for each of them must be determined, in every given case, with regard to the circumstances of the pannus itself on the one hand, and to the trachomatous changes of the lids on the other hand.

In a chronic trachoma case with a heavy hypertrophy of the tarsus, accompanied by pannus, the tarsectomy after Heisrath-Kuhnt gives usually, but not always, a good result for the pannus.

Modifications after Murakami or Mizuo of the Kuhnt's tarsectomy, which differ so far from the original method that bulbar conjunctiva is detached more widely than the latter, are also to be recommended for such cases. The reason why trachomatous pannus is so favorably influenced by the tarsectomy is an interesting problem for which many factors can be enumerated.

Above all, the absence of hypertrophied tarsus and of affected conjunctiva, which might have mechanically, or otherwise, an injurious effect upon the cornea, seems certainly to be one of them. But this factor must not be thought too much of, for the trachomatous pannus is not always parallel with the existence of hypertrophy of the tarsus or the intensity of trachomatous changes of the conjunctiva. It may be missed even in severe cases with hypertrophied tarsus; while, on the contrary, it may be met with sometimes in slight forms.

In recent years I obtained the most favorable results in the treatment of trachomatous pannus with hypertrophy of tarsus, by the modification after Mizuo of the Kuhnt's tarsectomy, in which the detaching of bulbar conjunctiva is carried out more widely than in the original method. Consequently it occurred to me that the most important factor which may exert a good influence upon the tarsectomized case of trachomatous pannus might be probably the detaching of the bulbar conjunctiva, performed during the course of operation.

From that point of view I tried in the following years the detaching of bulbar conjunctiva only as a treatment of trachomatous pannus, with or without hypertrophy of the tarsus, and especially in the former cases when the tarsectomy was out of question owing to diminution of the fornix, or when the pannus was clinically the essential disturbance, the conjunctiva having been almost restored from the trachomatous changes. The results were so excellent that I was pressed to describe my own method shortly in the following lines.

After disinfection of the eyelids and the conjunctiva, under general precautions 0.5 or 1.0 ccm. of 1 per cent cocain solution is injected subconjunctivally upon the fornix or upon the bulbar conjunctiva close to the latter. By this, insensitiveness and looseness of the conjunctiva may be achieved.

Then a flat incision is made by means of a thin and sharp knife parallel with the upper margin of the tarsus from the

inner to the outer canthus, thru the fornix or the bulbar conjunctiva.

Three suture threads are introduced thru the lower lip of the conjunctival wound, in the form of loops; and given to an assistant, who helps further the detaching of bulbar conjunctiva from the underlying tissue, by moderate traction of them.

The detaching of conjunctiva bulbi towards the cornea is achieved usually very easily with less bleeding by the help of Graefe's linear knife. Upon the limbus only, where the conjunctiva is intimately adherent to the subjacent corneal tissue, it needs a little more powerful procedure.

The detaching must be extended also towards median and lateral sides of the cornea, if the blood vessels run into the pannus from those sides.

The incision wound of the conjunctiva is sutured continuously towards inner and outer canthi by means of the middle loop. Fixation of each end of the suture thread on the skin of inner and outer canthus is made with adhesive plaster, and a bandage.

As after-treatment daily washing of the culdesac with a weak disinfecting solution is recommended, and if a strong irritation is caused, instillation of atropin is naturally required. Removal of the suture is done after four days.

If necessary, mechanical or medicamental measures must be further continued against the trachomatous changes upon the conjunctiva and fornix, after complete healing of the wounds.

I have twenty cases of trachomatous pannus in 13 patients thus operated, which have been observed long enough to determine the effect of my operation.

The blood vessels in pannus diminished gradually in all cases after this operation, and in the cases where one or one-half year has already elapsed they can be no more found even by means of a loupe. More or less corneal opacity in irregular form remains as residuum of the pannus.

Altho I am agreed with Prof. Onishi that there are some cases of trachomatous pannus, if few, where remissions spontaneously occur, I never saw a full disappearance of the blood vessels from the pannus in such cases. So the complete disappearance of the blood vessels in my operated cases must be ascribed to the favorable effect of the operation. No recurrence has been observed in any of my cases.

Recovery of the visual acuity after operation was as follows:

Visual acuity before operation	After one year
0.5	1.0 in 6 cases
0.3	0.7 in 5 cases
0.7	1.0 in 2 cases
Hand movement 1 m.	0.3 in 3 cases
After one and a half years	
0.5	0.9 in 2 cases
0.2	0.5 in 2 cases

Altho the cases are not very numerous, the result of my operation is to be mentioned as satisfactory; and I can conclude with safety, from my own experiences, that my method is not inferior, at least, to tarsectomy.

The favorable effect of my operation upon the trachomatous pannus is now recognized by other ophthalmologists of our country. Nagano has recently reported on his 21 cases of trachomatous pannus, which he had treated after my method with good results.

In the ophthalmologic clinic of the imperial university of Kyoto the detaching of bulbar conjunctiva is now recommended in the treatment of trachomatous pannus.

I suppose further that the detaching of the bulbar conjunctiva may be applied perhaps also as prophylaxis in cases where invasion of pannus can be expected; by destroying pathologic tissue already existing in and around the limbus; or, if not yet affected, by producing cicatricial tissue in the subconjunctiva, which prevents further advance of the trachomatous infiltration towards cornea.

DIFFRACTION IN THE HUMAN EYE AND THE PHENOMENA OF COLORED RINGS SURROUNDING LUMINOUS SOURCES.

CHARLES SHEARD, PH. D.

COLUMBUS, OHIO.

This paper from the Department of Applied Optics in the Ohio State University explains certain entoptic appearances; likely to be observed by the patient who may inquire with regard to their occurrence and significance.

Quite recently we have read a paper by Dr. R. Brudenell Carter,[1] of England, on "The Appearance of Color Spectra to the Aged." He describes in some detail the phenomena seen when looking steadily "at an ordinary electric filament light, about ten feet distant from the eyes." The light then appears to be surrounded by a vivid color circle of about two feet diameter, with the red border external, the blue internal, while the yellow and green are intermediate. "This band appears to be about six inches in width, so as to be clear of the light itself, from which its inner margin appears to be about six inches distant." If a lighted match is held at arm's length "the color circle around the flame appears to be about as large as a florin, while that around the full moon is very large and of very brilliant colors."

Dr. Carter concludes that the optical (refractive) condition of his eyes has nothing to do with the phenomena. He says, however, that if a strong light is brought sufficiently near his eyes the color circle disappears, but comes into existence again as the pupils expand when the light is carried away from the eyes. The color circles are also obliterated when looking thru a pin-hole opening. He concludes that the cause of the color phenomena is *"the diminishing refractive power of some of the ocular media."* After ruling out the vitreous humor, "atmospheric, secretory or compressive changes" the conclusion is reached that "the crystalline lenses are themselves the immediate causes of the phenomenon," and that these phenomena do not indicate diminution of or loss of lenticular transparency. In conclusion, Carter regards the color rings merely as an *"accidental result of unimportant lenticular conditions."* Since this paper was written, an excellent résumé of recent comments on this topic is given by Major Chance[3] in the "Digest of Ophthalmic Literaature."

The writer of this paper has been interested in these subjective phenomena of color rings surrounding luminous sources for some time, and has carried out some experimentation thereon. He has also included in his work on "Physiological Optics"[2] some of the essential facts which various authorities have been able to discover relative to the phenomena under discussion.

With such of Dr. Carter's statements as relate to the appearance, order of colors and so forth, we are in accord. However, we cannot agree with those statements which attribute the color

phenomena to diminished refracting power of some of the ocular media (presumably the crystalline lens according to Dr. Carter); nor again to the final conclusion that these rings are mainly the accidental results of unimportant lenticular conditions; for we shall present evidence to show that they are due to the superficial cells of the epithelium of the cornea or to the endothelium of the Descemet's membrane.

COLORED RINGS MAY NOT BE SEEN BY ALL OBSERVERS.

Likewise, the title of Dr. Carter's article—"The Appearance of Color Spectra to the Aged"—is, in our judgment, a misnomer; since age has, in and of itself, nothing to do with the phenomena, as we hope to show in succeeding paragraphs. These colored rings are not commonly observed because, as a general rule, the light source makes the surroundings too luminous. Or, in other words, there is not sufficient contrast between the light and its environment, such as is obtainable, for example, by striking a match in an otherwise darkened room. And for the further reason that these phenomena are not observed to exist, just as is true in the case of physiologic diplopia, unless the attention of the observer is directed to them. Furthermore, from the explanations which follow, it will be found that the intensity of illumination of the rings is only about two one-hundredths of that of the corresponding intensity of the first maximum (i. e., the original light source), hence, these rings falling upon portions of the retina external to the macula and having low intensity may not be visible in some cases and will not be observed in many others unless first described and then looked for.

The writer has observed these colored rings under favorable conditions for over ten years; and being still under forty years of age, these effects cannot be attributed, in his case at least, to the effects of age *per se* upon the crystalline lens, or other portions of the ocular mechanism. During this period of time his refractive correction has changed from +1.25 D. S. ⌒ +0.50 cyl. ax 90°, to +4.25 D. S. ⌒ +0.50 cyl. ax. 90°.

The attention of many students coming under the instruction of the writer, and of others coming under his observation, has been directed to these phenomena of colored rings; and with but few exceptions they have been readily observed. This has been true irrespective of the refractive condition, whether myopic, hyperopic or astigmatic, and irrespective of whether or not correcting lenses were worn. Hyperopic conditions apparently tend to make the phenomena (with respect to ring No. 1: see later discussion), more readily seen, however. This we believe to be due to the concentration of light, or sharpness of retinal image obtained by virtue of the small pupils, generally accompanying hyperopia; and the nature of the distribution of light upon the retina as affected conjointly by the condition of refraction and chromatic aberration. The size of the pupil, unless extremely and abnormally small, has no effect upon the phenomena. By this we mean that the phenomena are observable alike to those with large or small pupils.

They are also readily observed with ciliary and sphincter muscles relaxed, when viewing sources of light at large distances; or, again, when both are innervated, as in accommodating for such a source at close points. We are in agreement with Carter that these rings are not seen when the light is approached too closely, i. e., within a few inches of the face. The reasons are apparent: First, the contraction of the ring upon the approach of the source, and secondly, the submerging of the ring in the general central illumination surrounding the source. Also, these rings will not be seen when looking thru a small aperture, such as a narrow stenopaic slit. But the corona and striae radiating out from the light source will be found to be crossed at right angles by a series of parallel colored fringes, which arise from the diffraction effects observable thru any narrow slit. In this case the physical phenomena of interference and diffrac-

tion of light enter into the effects produced.

METHODS OF EXPERIMENTATION AND RESULTS.

One of the most serviceable and convenient sources of light to be used in observing the phenomena under discussion is the small lamp of a self-luminous retinoscope or ophthalmoscope. This light source is steady, small and brilliant when viewed in a darkened room.

If this, or a similar, luminous source is viewed at any convenient distance,

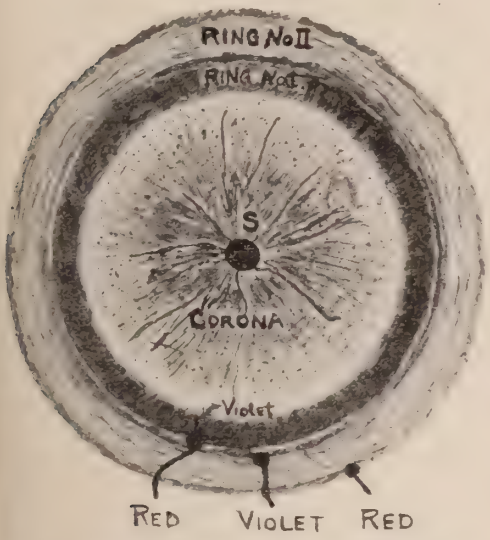

Fig. 1. Diagram illustrating relations of light source S, ciliary corona, and rings I and II.

the arrangement of colored rings and ciliary corona, so called, will be somewhat as roughly diagramed in Fig. 1.

The Ciliary Corona.—Surrounding the whole of the luminous source is a general luminous glow, with several prominent striae or rays shooting out in various directions from the central light. This phenomena is very striking if the light source is brilliant. The name of ciliary corona has been attached thereto. (Tscherning[4].) This ciliary corona is composed of an infinity of very fine, and ofttimes many colored radiations, which cross thru the whole of the luminous area. Its extent depends upon the intensity of the light source, or the luminous flux entering the observer's eye. Using an arc lamp, or the image of the sun reflected from a convex mirror, there will be found a diameter of the corona which may reach 8 degrees. An examination of these phenomena with monochromatic light causes some minor changes in their character. Under these conditions the corona presents the form of a luminous dust, crossed by few radial striae. Druault[5] says that, under such conditions, there may be seen quite near the luminous area one or two fine black rings, due to diffraction by the border of the pupil. That portion of the luminous "dust" or haze close to the light source appears to have a constant motion of the nature of contractions and dilatations, which probably correspond to changes of the pupil (Druault). However, we suggest that, if the corona is produced by crystalline lens fibers, these fluctuations may be due to small variations in the action of the accommodative apparatus.

Ring No. I.—Surrounding the ciliary corona will be seen the vividly colored ring (marked No. 1 in Fig. 1), presenting the colors from blue to red from the center to the periphery of the ring. If the luminous source is not very bright this ring forms the limit of the corona, but if its intensity is high the diameter of the corona may attain a value double that of the ring. Furthermore, these phenomena appear to be universal. Nearly anyone walking along a street lighted by gas or electric lights may observe them.

Ring No. II.—In addition, under conditions to be further discussed, there may be seen a second ring (marked Ring No. II in Fig. 1); somewhat fainter than ring No. I and closely bounding it, with colors arranged in a similar order. The writer has observed both of these rings simultaneously on a few occasions, when the light source was rather powerful and the pupil in a sufficiently dilated condition. The artificial dilatation of the pupil by cocain makes more probable the appearance of this second ring; but in addition it is generally necessary that the light source be brilliant, small and close at

hand. Otherwise the intensity of illumination of the ring by virtue of its size and the position and character of the retinal illumination are too low to make it visible. Upon the basis on which we shall attempt to explain these phenomena, namely *diffraction of light,* it will be shown that the intensity of this second maximum is only about one-third of that of the first maximum (i. e., the first ring), or about one two-hundredth of that of the original

data relative to our own eyes, since we are certain of fair accuracy in this case at least. The determinations of the diameters of the various portions of the colored ring No. 1 were made by the use of the small ophthalmoscopic lamp, held at distance of distinct vision, and observing (or marking) as nearly as possible the points cut by the various colors as seen upon a celluloid millimeter rule mounted just back of the lamp. No great accuracy in these

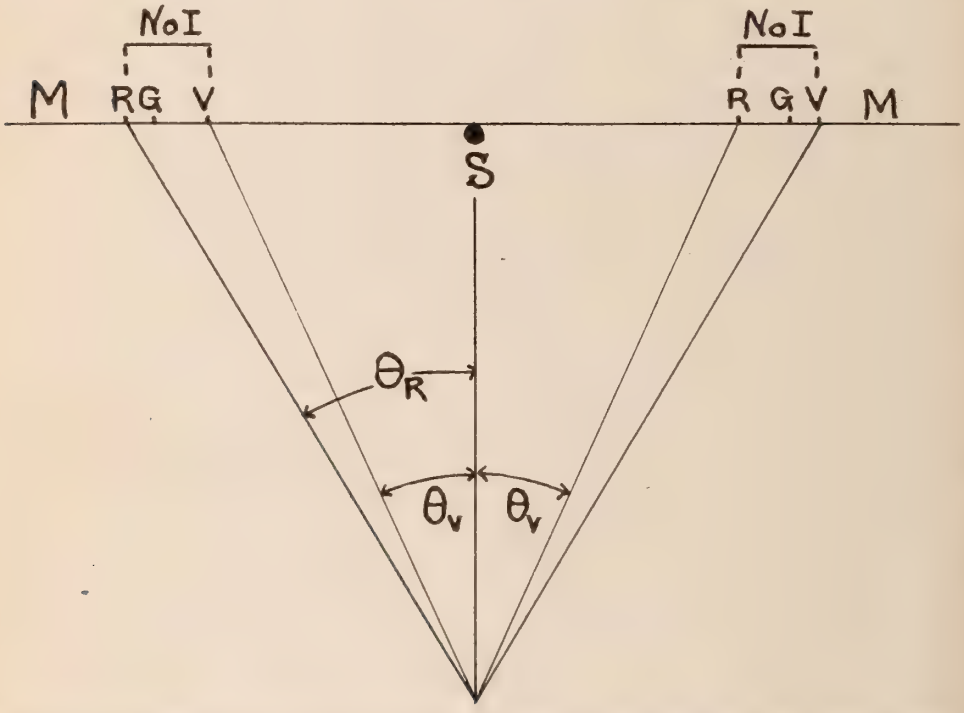

Fig. 2. Diagram illustrating the relation of the angles which determine the rings of the various colors, and their distance from the source of light. See text.

source. We have also to consider the fact that the situation of the retinal image is more peripheral in the case of the second ring, hence making its mental reception and interpretation less likely. The presence of a large pupil would, therefore, be conducive to greater flux of light and hence greater intensity of retinal stimulation.

DATA ON DIAMETERS OF THE RINGS.

We have made several sets of observations and obtained data given by several subjects, but prefer to tabulate the measurements can be claimed, i. e., within ten per cent probably, and yet the results were very concordant. Knowing, therefore, the diameters of the portions of the colored rings and the distance of observation, the angle, (θ), subtended at the nodal point of the eye by each of the colors could be found by calculation. The method is graphically illustrated in Fig. 2, in which S represents the source of light, $M\ M$ the millimeter scale, $V\ V$, $G\ G$ and $R\ R$ the diameters of various portions of ring No. I. The data for ring No. II

were obtained in a similar manner altho with less likelihood of accuracy.

A résumé of the experimental data is as follows:

TABLE I.

Ring	Angle (θ). Red λ=6500	Green-Blue λ=5000	Violet λ=4000
I	3° 40′	2° 40′	2°
II	8°	5° 40′	4° 20′

THEORY OF THE DIFFRACTION OF LIGHT BY CIRCULAR APERTURES AND CIRCULAR OPAQUE DISCS.

It is not our purpose in this paper to recopy the details of various mathematic proofs relative to the relations between slit width or space between particles, angle of diffraction θ and wavelength λ; but rather to take the final formulæ calculated in treatises on physical optics and apply them, with some explanations, to the subject under discussion. We shall also point out how the phenomena of interference of light enter into this problem. It is to be hoped that some digression will be pardoned in the interest of those who are not as familiar with the phenomena of diffraction and interference of light, as are physicists and those who are specialists in pure optics.

When light, diverging from a luminous point, passes by the edges of an opaque obstacle, systems of colored fringes are formed parallel to the edges of the shadows. Or if, for example, a knife-edge slit is cut in a piece of cardboard and a luminous source viewed thru the slit, there will be observed a series of parallel colored fringes, separated by dark strips, if a white light source is used. If a monochromatic source is used, then the fringes will be of one color and parallel to the lengthwise dimension of the slit. In the case of a circular disc or circular aperture, the fringes form a system of concentric circular rings. If we have a large number of irregularly distributed small equal apertures in an opaque screen it can be shown mathematically and experimentally that the diffraction pattern is the same as that produced by a single disc or aperture multiplied, in intensity, by the number of apertures (or discs).

By the principle of Babinet as applied to diffraction screens which are complementary, by which we mean a pair of screens in which the transparent portions of one are replaced by opaque portions in the other and *vice versa*,—it is found that the diffraction patterns are the same in the two cases. Hence circular discs or apertures are interchangeable in our theories.

Fraunhofer found that these colored rings could be produced artificially by looking at a source of light thru a plate of glass covered with fine particles of condensed vapor or with lycopodium dust. The condition necessarily imposed is that the globules shall be of sensibly uniform size. He also obtained these rings with a large number of small metallic discs of equal size, placed between two plates of glass; and found that the diameters of the rings varied directly as the wave length and inversely as the diameters of the discs. Further classical experiments by Verdet, Young and others give modified proofs supporting such conclusions. Hence we may conclude that any system of regularly spaced slits or obstacles, apertures or discs will give diffraction effects. Furthermore, in the case of diffraction by a large number of irregularly arranged circular apertures or discs, the phases between the parallel disturbances from homologous points vary in an irregular manner, and we have as much reinforcement as destructive interference in any given direction. The illumination at any point is the same as that produced by a single aperture multiplied by the number of apertures.

We have used the terms phase, interference and reinforcement in the foregoing sentences. Two particles, for example, are said to be in the same phase of motion when their displacements and directions of motion are the same; and two particles in the same phase are separated by a complete wave length, or by any whole number of wave lengths. Light of a certain wave length will be reinforced by light

of a similar wave length if they are in phase. If in opposite phase — that is, if one is executing a motion diametrically opposed to the other—they will interfere with or tend to annul each other. As a simple illustration of interference and diffraction, assume two narrow slits, A and B, as shown in Fig. 3, behind which is placed a source of light O, and consider the illumination at various points on the screen $M N$. Take the point Q directly opposite the middle of the slits; then light diffracted at A

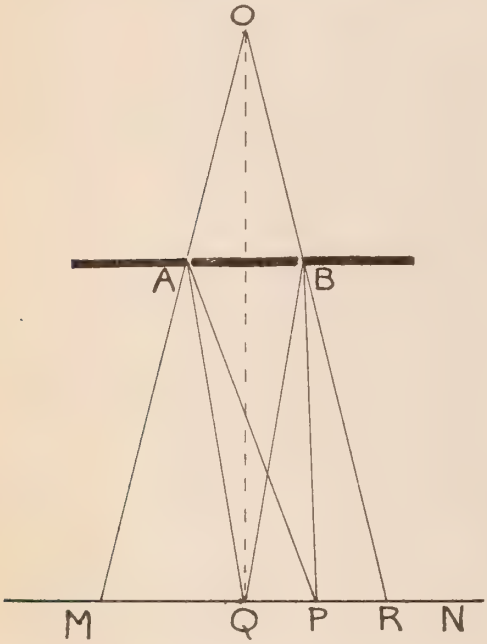

Fig. 3. Diagram illustrating formation of diffraction bands by two slits. See text.

(in such a direction as to reach the point Q, since light when diffracted by an aperture is not limited to one definite direction), and at B, meeting at Q, will be in phase, since the distances $A Q$ and $B Q$ are equal and contain an equal number of wave lengths or fractions thereof. Hence Q will be *luminous*. If we take the point P, for illustration, such that the difference between $A P$ and $B P$ is an odd number of half wave lengths (such as $\lambda/2$, $3\lambda/2$, etc.), then the wave motions reaching P will be in opposite phases and will interfere, producing darkness or a minimum of illumination. Again, if the point R is so situated that the difference between $A R$ and $B R$ is any number of wave lengths (such λ, 2λ, 3λ, etc.). there will then be a *luminous point* or *maximum of* illumination. Hence alternate bright and dark fringes are due to phenomena of diffraction and interference.

Let us now consider the case of diffraction of parallel beams of white light by a series of particles as diagrammed in Fig. 4. Let *a, b, c,* etc., represent the equal sized and equally spaced discs. The components of white light will then be diffracted or bent at the edges of the discs, the blue being diffracted the least and the red the most. The blue rays are represented by the longest lines, the yellow by the medium and the red by the shortest lines. The series of diffracted rays of each color will be mutually parallel.

Next consider the effect of a convex lens placed behind such a system of diffracting corpuscles. In cross-sectional diagram, then, each condition of focus of color with respect to the image, S_1, of the center source S is as diagrammed in Figs. 5, 6 and 7, in which S_R, S_Y and S_B represent the images for red, yellow and blue respectively. The amount of diffraction (θ), or bending of light increases proportionately with the wave length of light used. Figs. 5, 6 and 7 represent the point images obtained for definite wave lengths of light in one plane only. Hence, to complete the true representation of effects as they would actually appear in space, we have only to conceive of such planes (cross-sections), taken at every conceivable angle or to mechanically rotate the Figs. 5, 6 and 7 about $S S_1$ as an axis to obtain a condition of affairs precisely the duplicate of Fig. 1, in which there is shown a central source (or image in space) S surrounded by colored rings of varying angular widths depending upon the wave length (color) taken. The necessary elements for these diffraction effects we believe can be shown to exist in the eye; for we shall show that corpuscles of the proper diameters exist in the cornea, while the crystalline lens plays the part of the lens presented in the physical considerations of the statements relative to Figs. 5, 6 and 7.

To return, then, to the mathematics of diffraction of light by circular apertures or discs, we find that theory (see Preston's *"Theory of Light"*[6] and Wood's *"Physical Optics"*[7]) gives for the relation between the wave length λ, the angle of diffraction θ, the radius of the aperture or disc R, the order of the spectrum m (i. e., whether the first, second, etc., colored band), the equation

$$\sin \theta = \frac{m\lambda}{\pi R}$$

$$\text{or } m\lambda = \pi R \sin \theta.$$

This equation has the same form as that for diffraction due to parallel slits, such as is found in a plane diffraction grating, namely $m\lambda = d \sin \theta$. A comparison of the equations shows that d, the slit width, corresponds to πR, R being the radius of the aperture or disc.

Verdet[8] calculated the subjoined table for values of m/π corresponding to the first few maxima and minima.

TABLE II.

	m/π	Intensity
1st Max.	0	1
1st Min.	0.61	0
2nd Max.	0.81	.0174
2nd Min.	1.116	0
3rd Max.	1.333	.0041
3rd Min.	1.619	0

APPLICATIONS OF DIFFRACTION THEORY TO THE PHENOMENA OF COLORED RINGS.

Since we have the evidence of diffraction rings produced by some medium of the eye, and since θ and γ are known experimentally and m/π is obtainable from the above table, let us calculate the value of R, the radius of the disc or particle causing the phenomenon and see if there is any anatomic evidence of cells or structures of the eye fulfilling the conditions necessary for such diffraction effects. One or two specific examples are carried out somewhat in detail and the remainder tabulated as Table III.

Ring I. Blue-green. $\theta = 2° 40'$. $\sin \theta = .0465$. $\lambda = 5{,}000 \times 10^{-8}$ cm. (approximate blue) $= 0.5\ \mu$. $m/\pi = 1.333$. Hence from $R = m\lambda/\pi \sin \theta$, we find that $R = 0.0009$ cm. or $R = 9\mu$.

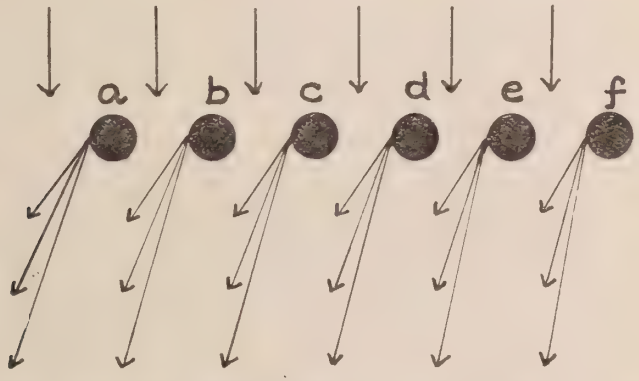

Fig. 4. Diagram of diffraction of light by a series of particles, separated by equal spaces. See page 190.

Ring II. Blue-green. $\theta = 5° 40'$. $\sin \theta = .098$. $\lambda = 5{,}000 \times 10^{-8}$ cm. (approximate blue) $= 0.5\mu$. $m\pi = 1.333$. Hence, substituting in $R = m\lambda//\pi \sin \theta$, we have $R = 0.00066$ cm. or $R = 6.6\mu$.

It is to be remarked at this point that the sets of readings and hence calculations upon ring I are much more likely correct than in the case of Ring II, in which difficulties of low intensity (S) make the determination of the angles (θ) less certain.

If, therefore, we accept the experimental data and results as being reasonably accurate and the applications of the theory of diffraction by circular apertures or discs as being permissible in the case under discussion, we arrive at the conclusion from the calculations tabulated above that Ring II is not a second order effect of which Ring I is the first order effect, but that it is due to a set of

particles or apertures of much smaller diameter as shown in set C, Table III. We conclude, therefore, that the apertures or particles giving rise to Ring I have an average diameter of 0.00184 cm. or 18.4μ and, in turn, those producing Ring II an average diameter of 8.3μ, unless this ring is due to second order diffraction effects of the same corpuscles, when calculation gives the average diameter of the particles as 0.00132 or 13.2μ.

Ring No. I.—We turn, therefore, to anatomic investigations to see if there is evidence of cells or fibres having diameters of the approximate amounts specified above. Schiötz[9] measured the dimensions of the *superficial cells* of the *epithelium* of the *cornea* and found sizes varying from 25μ to 40μ. He furthermore found that on exposing the cornea to the action of distilled water for some time he observed a beautiful system of rings of which the first corresponded practically to the Ring I. He remarks that it is a little smaller however, which is readily accounted for by the action of water upon the cells and apertures. These results of Schiötz are in close experimental agreement with the values of the diameters of the particles obtained by Druault in 1899. This latter writer found a value of $\theta = 2° 12'$ for sodium light of 5,900 t. m., which gives a value of D (diameter of the particles as an average), equal to 0.0025 cm. or 25μ. And again, Druault found, on looking through a dead cornea, a ring the dimensions of which differed but little from those of Ring I and which he claims was undoubtedly due to the *endothelium* of *Descemet's membrane,* for he could remove the entire epithelium of the anterior corneal surface without producing any effect, but the ring disappeared as soon as the endothelial layer was touched.

Ring No. II—The ring No. II Druault attributes to the crystalline fibers which are arranged in the form of a network or grating. The size of the openings or slits between these fibers can be calculated from the formula for a series of parallel rulings (i. e., plane grating), which states that $m\lambda = d \sin \theta$, where d is the slit width. If such is done, using Druault's data, we find that

$$d = \frac{m\lambda}{\sin \theta} = \frac{0.59}{\sin 3° 33'} = 9.5\mu$$

Anatomists[9] (see Norris and Oliver[10]), tell us that the superficial lens fibres measure from 0.0010 cm. to 0.0012 cm. or 10μ to 12μ. Hence, if these lens fibers were, in the main, parallel each to each, giving a series of parallel slits, it

would be justifiable to apply the formula given above for diffraction by parallel slits. However, we know that the lens fibers are parallel only in so far as the major portion of those forming any one sector of the "lens-star" may be considered parallel. Likewise, if these fibers were in the main parallel we should obtain the phenomenon of diffraction by parallel slits; which shows a linear spectrum and not circular as in the case of apertures or discs. Such a linear spectrum is not experimentally found. Hence the use of the above formula for parallel slits does not seem to be in order.

Druault says that ring No. I disappears completely if one part of the pupil is covered. In the case of ring No. II, however, such a procedure causes only the corresponding part of the ring to disappear, and the other part to become much more regular. Careful observations made by the writer on his own eyes, and the answers made by two or three competent observers, have evidenced the fact that Ring I does not disappear in toto as the pupil is covered; but that, instead, the luminosity of the whole ring is diminished and that the edge of the ring nearest the light source which is being cut off by a straight-edge shoved in front of the eye is made invisible first of all, if indeed any such effect actually takes place. There is theoretically no reason why the covering up of a portion of the pupil by a screen should produce different effects upon the diffraction phenomena, whether these phenomena be due to parallel slits, apertures, discs or what not; hence there is no good reason that we know of why Druault should have observed such widely different effects in the two rings. He reports that he succeeded in reproducing the phenomena with dead crystalline lenses.

If we grant that the lens fibers are not parallel in toto but by sectors, and that these sectors vary in position as we pass into the crystalline, then the total effect would be that due to meshes similar in form to fine meshed wire netting and we should expect the same general type of phenomenon as would be exhibited by such fine meshes. These we do not find experimentally. Moreover, if this second ring (No. II) is due to the

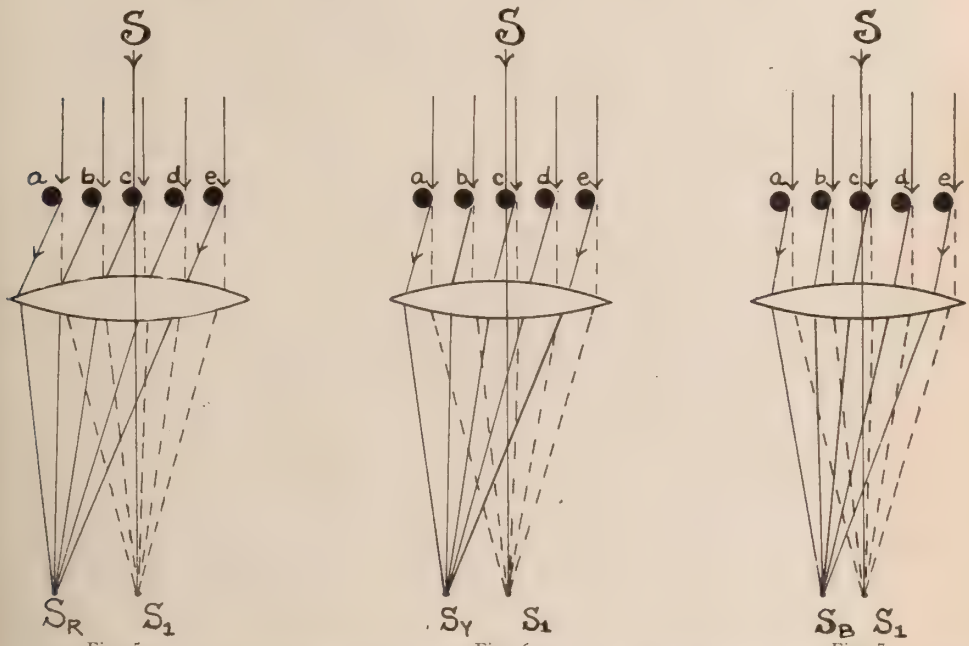

Fig. 5 Fig. 6 Fig. 7

Figs. 5, 6 and 7; diagrams showing formation of images of different colors from the light diffracted at three different angles. See p. 190.

crystalline lens fibers it is peculiar that this ring does not ordinarily appear without dilatation of the pupil. Furthermore, if the second ring is due to lens fibers, then it is presumably the first order spectrum and should have an intensity of about 1/20 (see Wood's *Optics* or Preston's *Light*) of the original light source; whereas ring No. I, having an intensity not in excess of 1/50 of the original light source, is readily seen. Hence ring No. II should be brighter and more readily seen if Druault's explanation is correct. Of course, there may be argued against this the fact of the difference in the retinal distribution of light in the two rings. However, the blue of the second ring lies very close to the red of the first one, hence such disparity would not be expected. The writer of this paper believes that the most logical source of the second ring is the layer or layers of deeper epithelium lying close to the anterior limiting membrane.

We have too little data upon the points taken up in the discussion of the preceding paragraph to draw any definite conclusions with respect to ring No. II. The writer is in hopes of interesting a colleague, who is a skilled anatomist, in this subject with the view to carrying out an extensive and joint series of investigations upon the seat (or seats) of these diffraction effects.

THE CILIARY CORONA.

The ciliary corona, with its luminous dust and striae, is without doubt due to the lens fibers in part and again in part to the lens star. These fibers and lens star are known to exist subjectively as the result of unequal refraction of light by the various sectors into which the crystalline lens is roughly divided. The pronounced criss-crossing of sectors of lens fibers in different layers, and the fine mesh appearance developed, serve admirably to account for the appearance or character of the luminosity immediately surrounding the light source.

Glaucomatous patients may see rings which resemble those described in the preceding paragraphs. In cases of glaucoma, however, these rings are larger and assume an angular diameter of 10° to 12°. Since the size of the ring increases as the distance between corpuscles or cells producing them decreases, Schiötz[11] attributes the origin of the glaucomatous rings to the deepest layer of the corneal epithelium. Experiments on pigs' corneae, so arranged that salt water could be forced into them, showed that a large circle of diffraction was produced when the liquid penetrated into the deeper epithelial layers.

CONCLUSIONS.

In résumé of the results detailed in this paper we note:

(1) The universality of colored rings and coronae surrounding luminous sources under fairly favorable conditions of observation.

(2) These rings are due to the diffraction of light by the constituent parts of one (or more) of the ocular media.

(3) The results of experimentation, based on the theory of diffraction of circular particles or discs, when compared with anatomic data indicate that the *first* (which is commonly the only one seen) ring is due to diffraction by the cells of the anterior epithelial layer of the cornea or possibly to the endothelium of Descemet's membrane (Druault).

(4) The *second* ring is evidently due to diffraction by particles of a smaller size than those which produce the first ring. The writer suggests the inner layers of the anterior epithelial portion of the cornea. This ring has been attributed by Druault to the lens fibers, but reasons are advanced indicating that such a view is not probable.

(5) The *ciliary corona* is without doubt due to the lens fibers and the *striae* to the lens star.

A TENDON TUCKER

Wesley Bishop, M. D.

MINNEAPOLIS.

This is a description of an instrument devised for rendering the tucking operation easier and more exact, and which can be used to measure the amount of advancement required. With illustration of results.

The correction of strabismus by a tucking operation has appealed to me but certain disadvantages apparent while using the various forms of tucker have provoked an attempt to modify the procedure by supplying an instrument which, while simplifying the operation, promises accuracy in the attempt to procure parallelism of the eyes.

Fig. 1. Tendon tucker, front and side view.

The performance of this operation under general anesthesia must of necessity entail more or less haphazard guesswork as to the result. To procure parallelism, the coöperation of the patient becomes an important factor; and to this end the operation should be performed under local anesthesia. It is here that we have met with our greatest trial, the pain caused by the traction on the muscle during the formation of the tuck being sufficient to seriously interfere with the patient's attempt at fixation. Again: The placing of sutures, with the muscle tightly stretched against the eyeball, is not without difficulties, especially when using certain forms of tucker.

The instrument herein described and illustrated (Fig. 1), I have found useful in shortening the externus; in shortening the internus, however, it will be found, like other tuckers, not so easy to handle on account of the lack of working space.

It is simple in construction, easy of application, and eliminates the objec-

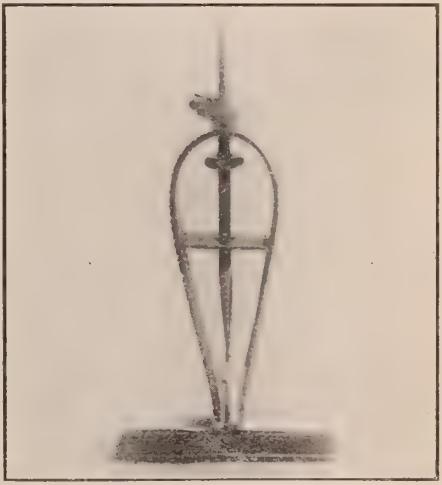

Fig. 2. Tendon tucker, showing raised loop of muscle.

Fig. Case before operation.

tions mentioned. Briefly it consists of a double standard, each leg of which terminates in a cross-bar base; to form the support for a flat hook, which operates between the standards, being raised or lowered by means of a thumbscrew.

OPERATION.

A few drops of four per cent cocain adrenalin solution are instilled at one minute intervals. As usual the conjunctival and capsular flaps are dissected back, exposing fully the muscle to be shortened, and upon this a drop of ten per cent cocain solution is now dropped.

The instrument is held perpendicular to the muscle, with the cross-bars forming its base squarely at right angles to the edge of the muscle, the hook being under it. To form the tuck the hook is raised by means of the thumbscrew, carrying upon it the muscle, as illustrated, thus raising a loop of muscle between the two standards.

With the patient looking straight ahead, the hook is raised until parallelism of the eyes is obtained, then a 00 pyoktanin catgut (20 day), suture is passed thru each side of the tuck at its base in the angle formed by the upright of each standard with its cross-bar base. The width of the standards separates the sutures and incidentally protects the central blood supply of the muscle. By reversing the thumbscrew the hook is now lowered and the instrument removed, the flaps are then sutured in place and the toilet of the wound completed.

It is astonishing, after noting the discomfort produced ordinarily by the tucking operation, to watch the formation of the tuck proceeding with absolutely no complaint from the patient. This we believe is due to the fact that during the formation of the tuck with this instrument, the traction on the muscle is in one direction; whereas with other instruments this traction is in two opposite directions, thus causing more pressure on the muscle fibers.

The placing of sutures is easy and accurate, as the upright standards offer no obstruction and the angle formed by each with its cross-bar base provides the determining point of suture.

When one prefers not to perform the tucking operation, the instrument may

Fig. 4. Case after operation.

be used to predetermine the position of sutures in making an advancement. In such case the instrument is placed with one standard directly over the insertion of the tendon and a tuck formed until parallelism of the eyes is obtained. A suture is then passed thru the base of the tuck, but going thru only that side of the tuck farthest from the tendon insertion. The instrument is then removed, allowing the tendon to flatten out again. The distance between tendon insertion and the suture measures the amount of shortening required.

The accompanying photographs, Figs. 3 and 4, illustrate an extreme case of convergent strabismus in which the left externus was shortened seven-eighths of an inch with absolutely no discomfort to the patient.

TRANSPLANTATION OF PORTIONS OF VERTICAL RECTI FOR ABDUCENS PARALYSIS WITH SUCCESSFUL RESULT.

RODERIC O'CONNOR, M.D.

OAKLAND, CALIFORNIA.

This paper records a case operated upon with a partly new technic giving the final result obtained, and an explanation regarding the outward rotation secured.

E. C., age 8, seen first July 29, 1916. Right eye squinting inwards, approximately 35° arc. Mother certain that this condition had existed since her second year, possibly longer.

Repeated examinations and trials failed to demonstrate an outward rotation, even to the primary position. This was not contrariness as she would rotate the other eye outward freely in following a test light.

There is no doubt therefore that the case was one of complete paralysis of the right external rectus; and she was con-

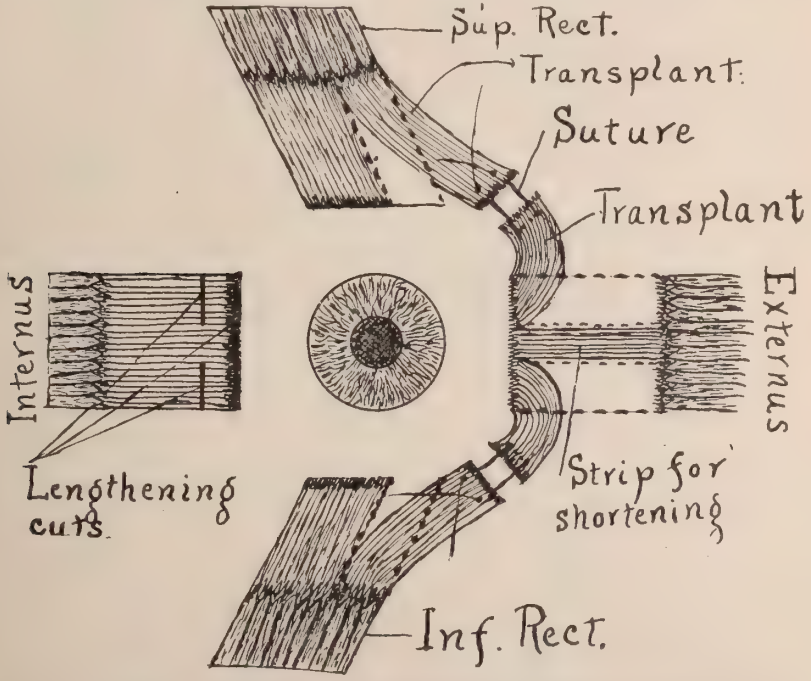

Fig. 1. The suture when tied draws the bared externus transplant well under the transplant from its respective vertical rectus.

sidered a suitable case for the transplantation operation. This was done on August 4, 1916, under general anesthesia. In as much as the technic differed in two points from that employed by others in similar cases, I deem it worth while to go into detail and to try to show it in a sketch projected to a common vertical plane. Fig. 1.

The externus and outer portions of the vertical recti were exposed thru a long incision concentric with the cornea and about 1 c.m. distant therefrom.

The outer third of each vertical rectus tendon was isolated with its superimposed capsule of Tenon, split far back, and shaved off the sclera. This I consider a very important point because in this way the fibrous attachment is included which will hold a stitch from slipping out. If the cut is made back of this point, the stitch will slip out along the parallel tendon fibers, unless tied so tightly as to cut itself out by necrosis.

The externus tendon was next isolated freely, *bared of its capsule* and divided lengthwise into three portions of equal width. The two lateral ones were then cut out free, well within the fibrous portion of their junction with the muscle tissue, for exactly the same reason that the vertical recti were shaved from the sclera.

The object of the above procedures was to permit a good overlap with the vertical recti slips, without undue tension on the stitches.

The central tongue of the externus was then shortened by my double hitch method as described in my paper before the ophthalmologic section of the A. M. A. at Detroit in 1916. This was done in hopes of relieving some of the tension on the sutures, as well as partially correcting, in itself, some of the squint.

The upper section of the externus was then united to the transplant from superior rectus, by a mattress suture inserted as shown in the sketch. Then the lower section to inferior rectus was similiarly united to the transplant from the inferior rectus. Conjunctiva then sutured.

The internus was not touched because I wished to prove positively that anything

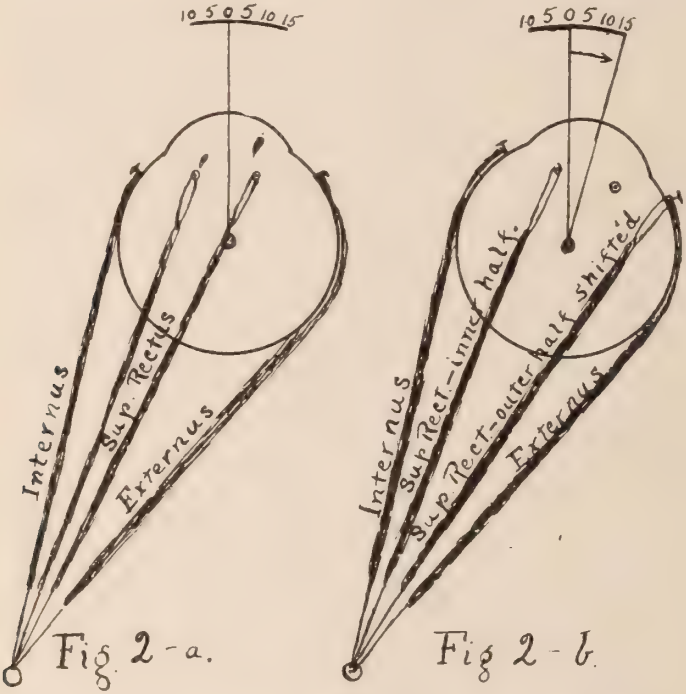

Fig. 2. Diagram showing influence of superior rectus (a) with normal attachment (b) after attaching external fibers to externus.

gained in position or outward rotation was due entirely to the transplant.

August 7th. Wound healing nicely. Marked improvement in position. Rotation not tested.

August 9th. A slight outward rotation now present in spite of swelling.

August 21st. Outward rotation now up to 25°. About 10° of remaining convergence. On this date therefore the internus was lengthened by my multiple cut method (similar to Verhoeff's.) See Fig. 1 lengthening cuts.

August 23rd. Eyes parallel. Outward rotation 35°.

August 25th. As on 23rd. Right rotation practically parallel except at extreme limit of motion.

August 28th. Outward rotation 45° on perimeter by reflection test. Wound healed and dressing omitted.

September 12, 1916. As on August 28th.

February 2, 1917. Rotation and appearance as on September 12, 1916.

April 27, 1917. As on February 2, 1917.

August 16, 1918. Esophoria 1° in primary position. R. rotates outward 35° easily. No diplopia within limits of glasses. So there is a perfect cosmetic result and for all positions near the primary, practically a perfect functional result.

When this case was presented before the eye section of the San Francisco County Medical Society, the general request was to explain the outward rotation. My idea on this point is as follows: It is well known that the vertical recti act as secondary abductors at all positions beyond 27° arc from the primary. This being so when we alter the mechanics of their attachments (1) by broadening, (2) lowering to a point closer to the equator we markedly increase the leverage in the outward direction so that rotation, by their action, will occur before the 27° position is reached. Figure 2 is a diagrammatic sketch of a model I constructed to explain the result.

Figure 2 (a) shows all muscles in balance for primary position, the muscles being thread rubber and the superior rectus made up of two threads, for diagrammatic purposes only.

Figure 2 (b) shows that a shift of the outer half of the superior rectus to the externus, without changing tension of any other bands, will abduct the anterior pole thru a 15° arc.

Another experiment balancing the muscles for a 10° convergent position, the best outward rotation possible in abducens paralysis, and then making the shift of outer half of the superior rectus, brings the anterior pole to primary position.

I think when we did add the power of a functional innervation to help the mechanical alterations, we had a sufficient explanation for the occurrence of outward rotation.

In another case done under a local anesthetic on an extremely unruly patient, I was not so successful, obtaining only 15° outward rotation. In this case because of his behavior the technics were not completed to my own satisfaction, as I was unable to secure wide enough transplants or to split them far enough back to allow of easy overlapping with sections from the externus.

NOTES, CASES AND INSTRUMENTS

CASE OF DOUBLE RETINAL SEPARATION IN TRENCH NEPHRITIS.

Lt.-Col. George S. Derby, M. C., A. E. F.

Authority to publish granted by Board of Publication, Surgeon General's Office.

Binocular retinal separation in nephritis is a comparatively rare condition and seldom, if ever, in civil life, does the disease terminate in the recovery of the patient. Furthermore, this condition has been seldom seen in so-called trench nephritis. It seems, therefore, worth while to put the following case on record:

W. S. 97 M. G. C., 19 years of age, entered 13 General Hospital, B. E. F. on January 2nd, 1918. He was placed

under the care of Captains Thompson and Keith of the R. A. M. C., who were doing special work on trench nephritis, and who, I believe, have reported this case, from the standpoint of nephritis, elsewhere. Patient had a severe bronchitis in December, 1916, and had rheumatism since. December 20th, 1917, he began to cough and had feelings of general malaise. Edema of the face appeared on December 25th, dyspnea on December 26th with pains in his legs and feet.

began to improve. A note from Captain Thompson states that at the beginning of his illness he had a marked edema of the conjunctiva which later disappeared.

On March 29th Captain Thompson asked me to see the case. Examination right and left showed a very marked neuroretinitis with some swelling of the disc and hemorrhages and areas of pigmentation thruout the fundus, together with whitish areas of degeneration. Changes were more marked

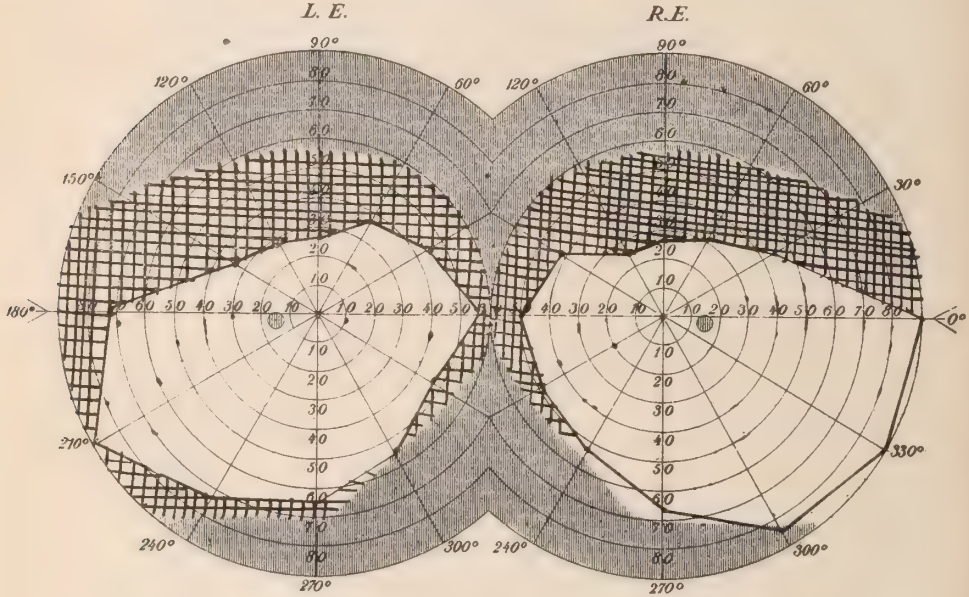

Fig. 1. Fields of vision in retinal detachment after improvement had begun.

Physical examination showed in brief; marked edema of face, limbs, and trunk, tonsils large, systolic murmur third intercostal space. Second sound plus. Dullness in posterior bases but no rales. Blood pressure of 145/85. Urine showed unmistakable evidence of acute nephritis and he ran a very severe course. For a considerable period, he was on the dangerously ill list.

On February 25th his eye grounds were examined by Captain Keith and obscuring of the disc margins was observed, otherwise nothing. About this time his sight began to get poorer and on March 16th he could not see much of anything. Subsequently his sight

in the left eye. In both the right and left eyes were found marked separation of the retina downward, reaching almost up to the macula region and the disc. Vitreous opacities were present in both eyes.

At this time the patient was markedly improved in general condition and he stated that his eyesight was considerably better. V. R. = 6/18, V. L. = 6/26. The fields showed contraction as indicated on the chart. At the time the patient was seen he was considered to be convalescent and ready to be returned to England. His urine had practically cleared up. I, however, prevailed on Captain Thompson

to keep him for three weeks longer and let me watch his eyes during that period.

During the next three weeks a diminution in the separation of the retina in each eye was observed and a continuous, tho small, improvement in the field of vision was noted. On April 23rd, a few fresh hemorrhages were present in the fundi, but the separation had disappeared in each eye. The limits of the field had practically enlarged to normal, being 42 degrees upward in the right eye and 46 degrees in the left. His vision at that time was, right 6/12 minus, and left 6/18 minus. A month after his arrival in England he was heard from and was apparently progressing well.

BILATERAL TUBERCULOMA OF THE ORBITAL LACRIMAL GLANDS.

HARRY VANDERBILT WÜRDEMANN,
CAPT. M. C.,

BASE HOSPITAL, CAMP LEWIS, WASHINGTON.

Without present access to the literature I can not recall to mind any cases of tuberculosis of the lacrimal glands; but surely such have occurred and have been noted.

Mrs. M. W., aged 40, colored, May 27, 1918, referred by Dr. Gates, of Seattle, complained of pressure upon eyeballs, headaches, poor sight and her unsightly appearance from protruding eyes, which had come on within two years.

Had syphilis four years ago with + + Wassermann, three years treatment, no present symptoms. No treatment for nearly a year. A well developed adult, negro-indian descent. Family history negative, except one sister had died of phthisis pulmonalis. Physical examination negative, except for chloasma of face and the condition of eyes.

Bilateral nodular tumors of both orbits in site of lacrimal glands, causing an apparent exophthalmus with "frog face."

V. R. 6/xx, L. 6/xx, R. + 1.50, ⌒ + 0.62. cy. ax. 90° = 6/xx. L. + 2.00, ⌒ + 0.62 cy. ax. 90° = 6/xx. No diplopia or muscular error, no fundus lesions, no real exophthalmus. Nose, throat and lymphatics normal. Wassermann negative, urine and blood negative.

The history practically excluding luetic gumma or osteoid changes, a tentative diagnosis of tumors of the orbit, possibly of the lacrimal glands, was made; and advice given of observation for a month or two before probable operation.

September 9, 1918. Minor Hospital, Seattle. Dr. C. R. Rion, ether anesthesia. Typical excision thru eyebrow incision on right side, of a very large, hard, nodulated orbital lacrimal gland in its entirety. September 17, 1918. Minor Hospital. Excision of a like tumorous gland from the left side; Dr. Fredk. Adams assisting, Dr. C. R. Rion, anesthesia. On neither side was the palpebral gland found involved, and on both sides the glands were shelled out by blunt dissection with but little difficulty. On the right side immediate union was found on first dressing on the fourth day; but one week later, altho the site of the operative area healed, a sulcus of about 3 cm. formed above the eyebrow which after two weeks showed no signs of healing, but was rather progressing, dissecting up the periosteum of the forehead. Then the report of the pathologist had come in showing unsuspected tuberculosis of the gland. The patient was then given 15 Tb. injections by Dr. Gates. Under these, together with diamzon ointment locally, healing was completed within eight weeks.

The left side, however, healed by first intention and no dressings were necessary after the 10th day.

REPORT OF PATHOLOGIST.

Macroscopic.—Gland 3x2x1 cm. in size. Markedly indurated but smooth and of even contour. Cross section discloses homogeniety of tissue resembling sarcoma.

Microscopic. — Connective tissue hyperplasia has widely separated the gland acini, until it has an adenomatous appear-

ance. Thruout is more or less dense small, round, cell infiltration. Here and there thruout entire section are remains and portions of ideal microscopic tubercles, consisting of epitheliod cells, giant cells and small cell infiltration.

More rarely an ideal microscopic tubercle is seen.

Diagnosis.—Tuberculosis of the lacrimal gland.

Date, September 19, 1918.

Examined by O. J. West, M. D.

REMARKS ON LACRIMATION AFTER REMOVAL OF THE LACRIMAL GLANDS.

There are two lacrimal glands for either eye, the major or orbital, the minor or palpebral. Removal of the latter almost totally restricts the formation of the lacrimal fluid, even in weeping, for the ducts are abated and the communication with the superior or orbital gland cut off, which then goes on to more or less atrophy.

Removal of the orbital gland but partially diminishes the lacrimal secretion, tho it is lower than the physiologic normal. Even true weeping occurs from grief or irritant stimulation.

Removal of both orbital and palpebral portions, or the palpebral gland alone, gives a dry eye for ten days or so; but soon compensation occurs, enough watery fluids being secreted to fully lubricate the conjunctiva.

SPASM OF ACCOMMODATION WITH DISTURBANCE OF OCULAR MOVEMENTS OF DENTAL ORIGIN.

GILBERT D. MURRAY.

SCRANTON, PA.

M. J.—Machinist, age 50 presented himself at the office on October 22nd, wearing an axious look, and said he had been obliged for the last week to quit work on account of his eyes. Patient complained that every time he looked away from the median line, either to the right, left, up or down he would become so dizzy as to almost fall. This dizziness was accompanied by severe pain in the eyes and temples. He could see his work without any difficulty when looking directly at it.

Vision was 20/20 each eye; presbyopic, one diopter. Exophoria, with plus 2 spherical, he could see one meter type to 12 or 13 inches. This type could not be seen beyond and within this range. While looking at a pencil held in different parts of the field he would almost fall off the chair from dizziness. Physically he was well nourished, though pale. Blood pressure 120. Urine, pupils, and fundus negative. Teeth had all been removed, except six incisors which were badly worn but looked so sound that the doctor who made the X-ray thought it a useless proceedure. Locomotion and hearing negative. Headaches for three weeks preceded the dizziness which brought him to the office. Both eyes showed incipient cataracts.

The skiagrams made of the teeth showed three large abscesses at the apices and one unerupted tooth immediately beneath the abscess. Both unerupted tooth and abscessed teeth were removed, and the man's headaches and dizziness were completely and promptly relieved. Plus spherical 2 D. lenses were ordered for near work. One meter type read then 8 to 22 inches.

It is not unusual to have iritis, eczema of lids, pain in eyeballs, etc., directly traceable to apical abscesses of the teeth, but this is the first case of spasm of accommodation noticed by the writer. The patient has been working one month and has had no return of the trouble.

SOCIETY PROCEEDINGS

SECTION ON OPHTHALMOLOGY, COLLEGE OF PHYSICIANS OF PHILADELPHIA.

November 21, 1918.

DR. S. LEWIS ZIEGLER, Acting Chairman.

Retraction of the Globe in Adduction.

DR. WM. ZENTMAYER presented a male, aged five years. At the age of seven months the mother noticed that the left eye "rolled about in the head," and says that this has persisted. With eyes in primary position there was a very slight narrowing of the palpebral fissure on the left side. The right was normal. See. Fig. 1.

In looking to the left, Fig. 2 (p. 204), the outward rotation of the left eye was limited. In looking to the right the left eye became retracted, a distinct space could be seen between the inner surface of the lower lid and the globe, and the palpebral fissure became distinctly narrowed. If the fixation was a little higher than the horizontal plane instead of the eyeball rotating strongly inward in adduction, when it reached a point just to the inner side of the middle line the eye shot strongly up. Fig. 3 (p. 204). If fixation to the right was a little below the horizontal plane the adduction was increased, but no supraduction occurred.

The fundus was normal and the refraction error was a low H. + As., against the rule. Turk's theory probably best explains this symptom-complex. His view is that the retraction is due to inflexibility of the external rectus muscle of the eye, showing the phenomena. The oblique movements of the globe Duane attributes to spasmodic contracture of the inferior oblique. Parker attributes the closure of the fissure to some peculiar associated movement produced by synergic action of the facial and oculomotor nerves.

The fact that in this case the upward shoot of the eye, while occurring at times when the eye is rotated directly to the right, manifests itself always and more strongly if the fixation is slightly above the horizontal plane suggest that this contraction of the inferior oblique may be due to a slight paresis of the superior rectus muscle of the opposite eye.

Fig. 1. Showing eyes in ordinary position.

Unilateral Vertical Nystagmus.

DR. ZENTMAYER showed a girl, aged fifteen years. She had measles at three years of age, complicated with otitis media purulenta on the left side, and esotropia of the left eye. Two years ago glasses were prescribed and the esotropia disappeared. The eyes are now stationary under cover. The left eye presented a vertical nystagmus. The movements were rather slow. The right eye by naked eye examination seems to be without nystagmic movements. Nor could they be detected with the ophthalmoscope until the pupil was enlarged and the optic papilla

Fig. 2. Showing retraction of L. E. in adduction. Note narrowing of fissure. P. 203.

closely watched when very slight vertical motion was detected.

Most of the cases of so-called unilateral nystagmus prove on careful study to be really anisonystagmic.

Pigmentation of the Excavation of the Papilla.

Dr. Zentmayer exhibited a colored woman, aged twenty-seven years, who came to Wills Hospital because of asthenopia, right-sided pain in the head and recurrent styes on the left side. In R. E. there was a small vacuole in the lens. The papilla was oval axis 95° and presented an unusually large excavation involving four-fifths of its surface. It was of the undermined type. Within the limits of the excavation on the temporal side there was a dark-gray crescent. The pigment seemed to be on the outer wall of the excavation. Contiguous with this, outside of the excavation, which extended up to the scleral ring, there was a conus of pigment of much the same tint. In the L. E. the appearances were identical. The refraction error is a low H. As.

Tuberculoma of the Iris.

Dr. Zentmayer showed a colored girl, aged six years, the history of whose case had not been unsatisfactory. The L. E. had been inflamed several weeks, attributed to a finger-nail scratch. There was a yellow-white oval mass 4x5 mm. occupying the angle of the anterior chamber and pressing upon the cornea. The cornea was very hazy and the epithelium shagreened. The pupil dilated on the temporal side. No detailed view of the fundus. T-n. Moderate ciliary congestion. Upper incisors slightly notched. Wassermann negative. von Pirquet positive. After the inoculation a small gray focus of infiltration appeared in the cornea. Animal inoculation will be performed to confirm the diagnosis.

Successful Extraction of an Opaque and Dislocated Lens.

Dr. Howard E. Hansell presented a woman, aged forty-five years, who

Fig. 3. Showing occasional upward shoot of L. E. in adduction. P. 203.

complained of gradually increasing loss of vision for ten or more years. A diffuse uniform opacity involved the entire lens of each eye. She had frequently sought surgical aid but had been refused.

A preliminary iridectomy on each eye was performed. A slight escape of vitreous followed in each eye, drawing attention for the first time to the dislocation of the lenses. The wounds

Fig. 4. Case II. Showing retraction of left eye in adduction. Note narrowing of fissure. P. 203.

healed promptly altho final recovery was slow.

The left lens was extracted a few weeks later by the wire loop with the loss of an insignificant amount of vitreous. Recovery uneventful. Final vision with correcting glass = 20/20.

The success of the operation was due in great part, if not altogether, to the large conjunctival flap, prepared before making the limbus incision, and drawn completely over the wound after the lens was extracted.

Dr. Krauss recalled the case of an aged man, who dislocated a cataractous lens into the anterior chamber, by slipping in taking a bath. The eye became painful. The lens was successfully removed with a loop with splendid visual results.

Acne Rosacea Keratitis.

Dr. J. Milton Griscom exhibited a patient who had complained of sore eyes during the past eight months. She was forty-seven years old, a heavy eater and suffered from chronic constipation. For the past two years she had suffered from a typical acne rosacea involving her nose, chin and cheeks, which appeared at about the time her menopause first manifested itself. When first seen the bulbar conjunctiva of both eyes showed numerous pinhead sized elevations adjacent to the cornea resembling phlyctenules with marked injection. On the corneæ near the limbus were several areas of superficial infiltration about 2 mm. in diameter surmounted by whitish necrotic tissue the size of a large pinhead. There was a band of superficial bloodvessels running from the limbus on both nasal and temporal sides. The remainder of the cornea was clear and the other ocular structures were free from disease.

Probable Intraocular Growth.

Dr. G. Oram Ring presented a preliminary report of an interesting case which involved a "Question of Diagnosis," as between malignant disease of the retina, and the other pathologic conditions, with which it can be confounded.

The patient, E. B., aged eleven months, has been under observation for two weeks only. The child had enjoyed perfect health from birth, until one month before being seen by Dr. Ring, when without the slightest premonition she had a convulsion. Two days previously, the patient swallowed a very hard cough drop, which was passed in forty-eight hours. During the same period the mother was suffering with influenza (temperature 102°), and had regularly nursed the child. With the onset of the convulsion, the child was immediately weaned.

Tuberculosis and syphilis were excluded, as was malignant disease in the family history. Barring the ocular con-

dition, the child was in all respects normal. The morning following the convulsion, the eyelids of the right eye were greatly swollen, and remained so for one week, at which time a "white skin" over the sight was observed by the mother.

At the initial hospital examination there was a moderate lid swelling and a general pericorneal and conjunctival flush. The cornea was slightly hazy, the anterior chamber quite shallow, the periphery of the iris retracted into a definite sulcus, especially down and out, the pupillary edge being pushed forward to the posterior corneal surface, the iris thus forming an almost right-angled curve. The pupil was vertically oval, the lens slightly hazy, irregularly swollen and pushed forward, especially in the center and to the temporal side. The reflex was pinkish white and proceeded from the anterior part of the vitreous. Across this mass ran a large and dilated bloodvessel. The tension was definitely minus, and transillumination gave only a faint reflex up and in.

Dr. Ring reviewed the points in differential diagnosis, of simple, retinal detachment, tubercular choroiditis, cysticerci, congenital anomalies, metastatic choroiditis, retinitis with massive exudation, retinitis circinata, and dropsical degeneration of the rod and cone visual cells (de Schweinitz and Shumway), and leaned to the diagnosis of retinal glioma, expressing the possibility that a metastatic influenzal toxemia may have played a minor role in inducing the ocular picture presented.

Dr. S. D. Risley said that Dr. Ring had kindly given him the opportunity to study the case in consultation. He had rarely seen any example of disease which gave wider opportunity for differences of opinion as to its essential character. Dr. Ring's careful and elaborate analysis had left little opportunity for additional comment. The sudden onset of convulsions with subsequent expulsion of a foreign body from the bowel, followed by the inflammatory conditions in the eye with loss of vision, due to an extensive detachment of the retina accompanied by objective signs of an underlying neoplasm opaque to transillumination, is certainly an unusual history. While there is the possibility that the intestinal conditions leading to the convulsions had caused a general toxemia which found local expression in the eye as a general retinal or subretinal edema; or possibly a choroidal hemorrhage which would be opaque to transillumination, nevertheless, careful study of the eye left the positive impression of the presence of a new growth.

In the presence of the extensive detachment of the retina, he did not feel that the diminished tension of the ball necessarily contraindicated the presence of a new growth, as he had many times seen examples of detachment of the retina, where subsequent enucleation had demonstrated the presence of a sarcoma, but which had nevertheless presented normal or diminished tension as part of the clinical picture. Notwithstanding this somewhat definite statement of opinion, he nevertheless felt that the questionable diagnosis could be rendered definite only by the laboratory study of the eye, and he hoped that Dr. Ring would at a subsequent meeting of the Section inform the Fellows as to the pathologic finding.

Dr. Zentmayer said there were two statements in Dr. Ring's paper which were open to discussion. Dr. Ring states that detachment of the retina could be excluded because of the absence of trauma and of a refraction error of sufficient degree to cause it. These, however, were not all of the causes of detachment and there was one pertinent to the diagnosis in his case. Nettleship first described the condition, and there have been several since reported, one by Dr. Zentmayer in which the picture of glioma was due to detachment of the retina the result of the subretinal presence of a serous fluid containing cholesterin, the probable remnants of an extension hemorrhage. These cases have usually a history of a preceding exanthem, commonly measles. As to the value of the intraocular T. in diagnosis Dr. Zent-

mayer's personal experience was at variance with that of many clinicians. He had never met with minus T. in an eye with a well-defined intraocular tumor, unless, perforation of the coats of the eye had occurred or an iridocyclitis had developed. He had, however, met with plus T. in pseudoglioma. Personally, therefore, he would consider a decided plus T. to strongly favor a diagnosis of glioma and a decidedly minus T. to almost surely exclude this diagnosis.

Dr. Hansell said the careful clinical analysis of the pathologic changes so graphically depicted by Dr. Ring point to but one interpretation, namely, glioma of the retina. He examined the patient at Dr. Ring's request upon two occasions at an interval of a few days. During that time the disease had perceptibly advanced. The vitreous body was completely filled by a white mass, the lens pushed forward until the anterior chamber was almost annihilated. The rapid growth, the characteristically white appearance of the tumor, the absence of history of any of the usual causes of pseudoglioma, made the diagnosis almost certain.

J. Milton Griscom, M. D.,
Clerk.

JOINT MEETING OF THE CHICAGO OPHTHALMOLOGICAL AND CHICAGO MEDICAL SOCIETIES.

December 18, 1918.

Fourteen Points Concerning Ophthalmia Neonatorum.

Dr. Frank Allport had endeavored to formulate fourteen points which he considered especially important in connection with this subject.

First: Ophthalmia neonatorum is responsible for about 20 per cent of the blind in the United States, and for about 25 per cent of inmates of blind asylums.

Second: It costs about $30.00 a year to educate an ordinary child, and about $400.00 a year to educate and care for a blind child.

Third: There are about fifty blind schools in the United States, costing about $2,000,000 a year to maintain.

Fourth: Ophthalmia neonatorum costs the United States about $7,000,000 per annum in actual money.

Fifth: Next to optic nerve atrophy, ophthalmia neonatorum is the most prolific cause of blindness in the United States.

Sixth: The Credé treatment for all new-born children would almost entirely eliminate this disease and its dreadful consequences from the world.

Seventh: The use of this evidently necessary treatment is by no means universal, and its omission is not confined to midwives. In order to accomplish its purpose the use of this treatment should be invariable. It should be understood that gonorrhea is not the only condition that will produce this disease, but that it may occur from other and nondisgraceful causes.

Eighth: Midwives are a financial and sociologic necessity. Fully one-half of the confinements are attended by midwives. If it were not for these midwives most of these cases would be merely looked after by friends and relatives. Midwives should be educated, examined, licensed and inspected, and should always call in medical assistance in complicated cases.

Ninth: Births should be compulsorily reported within a few hours. The ocular condition should be reported, and the physician should state whether or not he has used the prophylactic treatment.

Tenth: Suitable laws should be passed in each state providing for the invariable use of Credé prophylaxis in all newly born children, and proper penalties should be imposed for the nonobservance of such instruction. Every legitimate method of educating and enlightening the people, the midwives and the doctors should be encouraged.

Eleventh: While not prophesying as to what the future may produce in the way of prophylaxis, it is reasonably certain that at present there is no remedy that can take the place of nitrat of silver. It alone has stood the test of time. In order to provide free and re-

liable silver solutions some states and cities prepare and distribute fresh and carefully compounded solutions to doctors and midwives on application.

Twelfth: One almost insurmountable difficulty in the way of proper treatment of ophthalmia neonatorum is the paucity of resources in combatting the disease. A small hospital should be established in every large city for the prompt reception of such cases. Or it should be clearly understood by health officers, doctors, midwives, visiting nurses, etc., that certain hospitals will receive such patients, in special wards, at any time, day or night, and undertake to provide expert medical attendance and proper care.

Thirteenth: Health departments in the larger cities should employ an experienced eye nurse to search out and follow up cases of ophthalmia neonatorum, and to see that immediate action is taken when cases are found.

Fourteenth: I believe that great benefit can be accomplished by the free and frequent distribution of brief and pointed pamphlets, printed in several languages, by some central organization, such as the National Committee for the Prevention of Blindness.

The paper contained a sample of what Dr. Allport believed should be covered in such a leaflet.

Discussion.—Dr. Richard J. Tivnen emphasized some of the points brought out by Dr. Allport and thought the outstanding feature of this disease was that it could be prevented. This meant that 25 per cent of the blindness among children could be eliminated, and it was a reflection that even one of these cases, in the light of modern treatment, should have been blind. At one time our Committee on the Prevention of Blindness thought that the best way to prevent ophthalmia neonatorum was thru legislation, but it was soon found that this was a very discouraging and unsatisfactory way of meeting the problem. We then turned to what we afterwards found to be the best plan—education. This "education" should come from within the profession as well as from without.

The one thing that had proved most effective in preventing this disease was the so-called Credé method of prophylaxis, which was very simple and could be carried out with some simple instruction by anybody. It simply meant the instillation in the infant's eye, following birth, of a drop of 2 per cent solution of nitrat of silver. Many of the obstetric textbooks, however, were lax in their instructions about carrying out this procedure. They failed to say that the only time the solution should be *dropped* in the eye of the infant was immediately after birth and if it required further treatments it was applied to the lids. He knew of one case where it had been dropped in the eyes four or five times a day for a considerable period with disastrous results.

The Credé preventive was the accepted treatment for the prevention of infection, and if the profession would adopt it universally it would be a long step forward in the elimination of blindness due to ophthalmia neonatorum. Education might also with advantage take the form of a more intimate coöperation between the specialists in diseases of the eye and the general practitioner in the handling of these cases, and in the early recognition of the disease. It was idle to talk of preventing blindness if the cases were not recognized and treated early.

The ulcer of the cornea which was so destructive seldom appeared for several days, and was usually preceded by redness, edema and discharge. It could be said that a reddened, discharging eye with a swollen eyelid in the baby at birth was more than suspicious, and should always be investigated and treated. Every eye-man on the staff of every general hospital should insist that he be granted the opportunity to deliver a course of lectures on this subject to the nurses, and public lectures with stereopticon slides which would particularly appeal to the people would have a wonderful effect in bringing about the recognition and dangers of this disease.

Dr. N. C. Nelson reported on the treatment used in this class of cases at the Illinois Charitable Eye and Ear Infirmary. He stated that they saw

many cases that had been treated with the Credé method, and yet developed ophthalmia neonatorum. This was due to one of two things, either the improper application of the silver nitrat solution, or the eyes were infected postpartum by the person delegated to care for the mother and babe. In more than 70 per cent of their cases the infection began from two to ten days after birth, about 50 per cent occurring on the third or fourth day and the other 20 per cent from two weeks to two months after birth.

Owing to their cases coming to the hospital so long after infection began, the percentage in which both eyes were involved was very high, 84 per cent, as compared with only 6 per cent R. E. and 10 per cent L. E. This proved how important it was to have the treatment early. Nearly all cases with only one eye involved came for treatment within the first week and of those only 2 per cent developed infection in the other eye.

In the very acute cases ice was used to the eyes from two to three hours, repeated every four hours for the first twenty-four to thirty-six hours. He did not consider it good policy to keep the ice on constantly as it lowered the vitality of the cornea and thus defeated its purpose. The mother was instructed how to bathe the eyelids with pledgets of cotton soaked in warm boric acid solution every fifteen minutes. The eye was irrigated with great care every two hours in the beginning and later every four hours, every possible precaution being taken to prevent injury of the cornea. A one-half per cent solution of atropin was used three times daily to cure the iritis or prevent its development.

Some form of silver was usually dropped in the eye three or four times daily without everting the lids. As soon as three negative smears were obtained the patient was dismissed and given a mild solution of zinc and boric acid to be used at home several times daily, returning twice a week for four weeks. In treating ulcers of the cornea they generally used alcohol or tincture of iodin and seldom the thermic cautery.

He thought it made little difference what was used. The important factors were to get the cases early, keep them clean, and handle the lids carefully during treatment. If this was done the majority of cases would recover without complications.

Dr. A. A. Hayden endorsed everything Dr. Allport had said. Dr. Agnew, of New York, a long time ago devised a fairly permanent solution of silver nitrat, containing to the ounce one dram of sweet spirits of niter, which kept the solution stable for a number of months. He believed it was not necessary to evert the lids if a lid elevator was used thru which the irrigation could be made. This elevator contained a canal with two or three openings in the margin of the end which was placed under the upper lid, and allowed free irrigation. The accumulation of pus could be decreased by frequently anointing the lids with a 1:5000 bichlorid solution. Specific instruction should be given in works on obstetrics not to irrigate the eye with salt solution before using the silver nitrat, as was often done.

In his opinion ice should not be applied for more than ten or fifteen minutes at a time, application being made as often as every two or three hours. The thing that gave most relief after the lids became enormously swollen was an early canthotomy. Nurses and doctors should use every possible preventive measure to avoid personal contamination. Large glasses should be worn in the treatment of these cases, as was done in various operations for pus tubes or other operations in which the gonococcus might be present, and the hands should be most carefully washed before and after the treatment.

Dr. Henry Mundt was convinced that education was a very important factor in the prevention of gonorrheal ophthalmia. Where education failed the fear of God placed in a man's heart might be of some value. He cited a case against a hospital in this city in which argyrol was used in place of silver nitrat in which the hospital and

physicians were assessed in the neighborhood of $14,000. Men who formerly believed that a substitute for the Credé method could be used were now convinced that this should not be attempted. In a great many hospitals if physicians wanted anything else used it was necessary to give a written order to that effect, and most men would think twice before doing this. He agreed with Dr. Hayden that an external canthotomy was one of the most helpful things in preventing, also in the treatment of corneal ulcer.

Dr. John M. Lipson stated that in fifteen years' experience only one child had developed ophthalmia neonatorum. All of his cases were treated exactly alike by means of the Credé method and he did not understand why this child developed the disease, unless it was the only one in which the gonococcus was present. It was his opinion that the cases that did not develop the ophthalmia neonatorum did not have the gonococcus.

Dr. Thomas O. Edgar, Dixon, Illinois, reported an unusual case seen by him during the past year and a half. A two-months-old baby was brought for examination with a history of having what was presumed to be two per cent silver nitrat dropped into its eyes six or eight hours after birth by a practical nurse. The baby, previously quiet, cried severely during the night. About 4 A. M., eight hours after the use of the silver nitrat, the right eyelids began to bleed and continued to do so all that day, becoming much worse in the second evening, and, in spite of the employment by a second doctor, who had been summoned, of various means to stop the hemorrhage, including the use of cotton packed under the lid and the injection of some kind of serum into its leg, the bleeding ceased only after a grave loss of blood during the next twenty-four hours.

Three days later, the right eye bled again for several hours. During this time the eyelids of the right eye were much swollen. When first seen by Edgar at the age of two months the upper eyelid of the right eye was slightly congested and showed a tendency to invert, while the cornea exhibited a central whitish opacification, superficial but also extending into the deeper layers. This area in its densest portion was approximately round in shape, about five millimeters in diameter and showed several pin point brownish areas, probably due to argyrol. The left cornea was clear. A bacteriologic smear from the conjunctival sac in each eye proved negative. The eyelashes for a definite portion of the border of the right upper lid extending eight millimeters temporalward from the center of the lid border continued during the next year, at times, especially when the baby cried, to rub the cornea and even caused a faint pannus in the upper peripheral portion.

The question of hemophiliac diathesis having arisen in this case, the test of the coagulation time and hemoglobin was more than once taken during its first year; and together with a general physical examination by a competent internist proved normal. There was no history of hemophilia in the family. When the child was fourteen months old the parents consented to a modified Hotz operation for the circumscribed entropion, with an excellent cosmetic and therapeutic result. When seen four months later, the cornea had become much clearer. According to the history as given it is not certain that there was any bleeding from the left eye; if present, it must have been insignificant; in explanation of which it is possible that none or little of the medicine was gotten into the second eye.

It was thought by some of the parties concerned that there was the possibility of an error in the strength of the silver nitrat. The pathogenesis is not, then, satisfactorily established. This case is not cited against the use of the Credé prophylaxis for ophthalmia neonatorum, but to show that, like any other procedure, it must be used correctly and with all due precaution.

Dr. Charles H. Long said that when in general work he had taken care of some 1,500 obstetric cases, and all of them were treated with a 1 per cent

solution of nitrat of silver. He never had a case of ophthalmia neonatorum. The cases of this disease which he saw were from the practice of midwives and he thought education among midwives should be brought about. Most of them knew nothing of antiseptics and were strangers to what should be done to prevent ophthalmia neonatorum. In his opinion it would be an excellent plan for health officers and medical societies to appoint one meeting a year to discuss this subject and invite midwives and nurses to be present. In this way much could be done toward educating them along this line. It seemed necessary to have midwives, for without them many cases would have no care at all.

Dr. Clarence Loeb stated that oculists objected to the licensing of optometrists because they did not possess sufficient skill and knowledge to do their work properly, and he believed the same thing should hold true of obstetricians and midwives. The profession of midwifery should not be tolerated in this day of charitable physicians and so many free dispensaries and hospitals. In many states it was obligatory to report all sore eyes of infants and then the health department saw that the cases were properly treated. The Credé method was all right as far as it went, but all cases should be reported with a statement of the kind of treatment used.

As to discussing the subject, this had been tried in Missouri a couple of years ago, but they had great difficulty in getting the members of the medical societies to provide a place for such discussions, and the meetings were not well attended. The profession and public were lukewarm. Those who did attend probably learned a great deal, but the majority of them forgot it very speedily. If proper pamphlets could be given to the women at the psychologic moment, shortly before the birth of the child, they would probably be impressed and insist upon proper treatment. In his opinion the best plan of education was to teach this subject in the medical schools in a more complete manner, including the prophylaxis. This should be one of the questions on examination day and the men would know, at least at graduation, how to treat and how to prevent it.

Dr. Allport, in closing, said that in most of the laws which had been enacted in the different states it had been specifically stated that all cases of red eyes should be assumed to be ophthalmia neonatorum and so taken care of. His paper dealt with the prophylaxis and not the treatment of ophthalmia neonatorum, which was a large and entirely different subject. He did not wish to be understood as stating that the only thing to be done to prevent this disease was to use nitrat of silver. He believed that was at the present time the only drug to be used, but many other things should be taken into consideration, as shown in the leaflet which he had compiled for distribution.

Prevention begins before birth and the vagina should be properly cleansed so as to provide as clean a passage as possible for the child and other precautions taken. There are various reasons why nitrat of silver did not always prevent ophthalmia neonatorum. It must be properly used; in many cases where the treatment failed the solution did not reach the conjunctiva at all. The solution must be absolutely reliable. He did not know what produced the unfortunate results in the case reported by Dr. Edgar, but it was not due to the nitrat of silver if it was in proper condition when it was used. Dr. Nelson spoke of the late invasion of ophthalmia neonatorum, but in his opinion if this occurred more than three or four days after birth it was due to something that happened after birth and was not a true ophthalmia neonatorum.

As to midwives, Dr. Loeb thought they should be classed with optometrists and he sympathized with that. Theoretically midwives should be abolished; they are not competent to take care of children at birth, but children are being born at a great rate each year and the doctors are not able to take care of them all even if called, and poor people do not indulge in doctors very much, anyway. In his opinion it was not

practical to attempt to abolish them, and as a practical matter they must be educated and retained. The best way to get along with the subject is to try to make the midwives better and educate them as much as possible. With this object in view it might be a good plan to invite them to attend meetings at which this subject is discussed.

In the matter of education, legislation went a long way and was very helpful, but people in general must be educated to understand about these things. He was for a number of years general chairman of the Committee for the Prevention of Blindness in connection with the A. M. A. At that time they had local chairmen in every state in the Union except three, and there was an organization for the promulgation of knowledge concerning the conservation of vision. Meetings were held to educate the people about the care of their eyes and a series of twenty leaflets were published and distributed throughout the states; lectures were given to nearly 2,000,000 people and in the neighborhood of 200,000 pamphlets were given out. It was his opinion that this campaign did a great deal of good. It was too much to expect perfection, but we should keep hammering and hammering away and be satisfied with doing all the good we can.

Trachoma.

Dr. Clarence Loeb stated that this disease had been endemic in Europe since antiquity, although it had been believed that it first appeared in Europe at the beginning of the nineteenth century. It was an interesting commentary on the improvement in prophylaxis and hygiene since that time to note the rarity of the disease in the armies engaged in the present war. With the possible exception of the negro, no race and no land is free from trachoma, but certain areas seem to be more infected with it than others.

In the United States it was especially prevalent among the Indians, in the mountains of Kentucky, and in the eastern centers of immigrant population. This wide dissemination of the disease was important for two reasons: first, because its destructive effect upon the eyesight was daily adding to the quota of the blind of every nation; and, second, because its infectious character made even a single case a source of danger to the community in which it existed. It had been estimated that 9.4 per cent of all blindness was due to trachoma, and that this disease could be classed among the preventable causes of blindness.

It was a disease primarily of the conjunctiva, although its influence in causing blindness was exerted through the complications affecting the cornea. Its pathologic anatomy consists in numerous inflammatory infiltrations of the conjunctival tissue. These enlarge and form the "granulations" which are characteristic of the disease. These may be present as isolated follicles, more or less hidden by the hypertrophied conjunctiva which takes on a papillary character, or the follicles themselves may be so numerous as to be the predominant feature of the disease. Finally, there may be any stage of gradation between these two forms.

As to etiology, little could be definitely stated. The disease is highly contagious, but its transference is brought about only by actual contact of the nonaffected eye with some article contaminated by the secretions of the affected eye. While not contagious in the same sense as influenza and similar diseases, it is probably caused by some microorganism, the nature of which has not been satisfactorily settled.

The symptoms of trachoma vary with the stage of its development; in the beginning the patient may be very little inconvenienced or there may be fulminating symptoms. The cicatricial stage is marked by the appearance in the conjunctiva of fine, white lines, which increase in length and width, forming a network in whose interstices the remnants of conjunctiva appear as red islands. The amount of scar tissue depends on the age of the process, the severity of the disease and the lack of treatment or its improper character.

As the scar tissue contracts the cul-de-sacs are obliterated, adhesions between the ocular and palpebral conjunctiva develop and the whole conjunc-

tival sac shrinks, drawing the lids close together, limiting their movements and narrowing the palpebral orifice. Eventually the margins and lower parts of the lids will be curved inwards against the eyeball, a condition called entropion. The constant rubbing of the cornea by the eyelashes causes, subjectively, intense pain; and objectively abrasion of the corneal epithelium with opacification of the cornea from a traumatic keratitis, or the formation of ulcers. Whether the result of the trichiasis and entropion is corneal opacity or staphyloma, or both, the net result is the same—complete or almost complete loss of sight.

The treatment of trachoma consisted of three parts, prophylactic, medicinal and surgical, the first of which was the most important. The prevention and ultimate total eradication of this disease depended upon the ability to isolate the affected individual completely. Places where large numbers of people are in more or less intimate contact should be kept under medical inspection repeated at frequent intervals. As to medical treatment, each physician used the treatment which had proved most successful for him. One of the best remedies was a 1 per cent solution of silver nitrat, especially where there was profuse discharge or corneal ulcers.

Dr. Loeb found that the best results were obtained in all stages by the use of the copper sulphat pencil, applied to the upper fold of transmission once a day so long as any granulations were present. When these were gone it was replaced by 2 per cent zinc sulphat, one drop daily. Throughout the disease the eyes must be cleansed frequently with a saturated solution of boracic acid, which was applied with pledgets of cotton well moistened. If iritis or ulcers develop the use of atropin is indicated, together with smoked glasses, which are also of benefit where there is much photophobia.

In the surgical treatment, in the beginning of the disease some form of expression of the granulations is to be employed, followed by the usual medicinal treatment. In the cicatricial stage the surgical treatment is to be directed against the effect of the trichiasis and entropion. Sometimes a simple canthoplasty is sufficient, but usually it is necessary either to move the lashes further away from the lid margin, or to create a new lid margin, or even to remove the tarsus. An optical iridectomy may be of service in cases of corneal opacities.

Discussion.—Dr. H. W. Woodruff, Joliet, Illinois, believed that in the beginning of trachoma, when the typical granulations were present, there was a very definite indication for the operation of expression; and the results were so marked that there was no question about its value. After reaching the cicatricial stage with deformities of the lid there were certain definite conditions to deal with. The narrowed palpebral fissure was dealt with by canthotomy. The ingrown eyelashes were dealt with by the well known Hotz operation or by skin grafting or by marginal mucous grafts. The operation of tarsectomy he considered the greatest triumph of the surgery of trachoma.

The one characteristic feature of trachoma was its tendency to relapse. One theory was that pannus was due to the rubbing of the lid on the cornea and another that it was due to trachomatous disease on the cornea, but there was no question that the rubbing of the scar tissue of the lid was a very prominent factor and the operation of tarsectomy was indicated in these cases in which relapses occurred where there was not too great an atrophy of the conjunctiva of the cul-de-sac. The operation was so comparatively simple and the results so certain that it seemed as though anyone who had had experience with trachoma cases and their relapses would be a strong advocate for it. It was important that it be done with great care in order to preserve the muscular tissue; and nothing be removed except the tarsus and overlying conjunctiva. In removing the tarsus it was important that it be removed near the lid border as possible. At least near enough to take in the longitudinal scar which corre-

sponded to the sulcus subtarsalis, because that was the particular point where the deformity began and where there was nearly always a linear scar.

ALFRED N. MURRAY, M. D.,
Secretary.

COLORADO OPHTHALMOLOGICAL SOCIETY.

January 18, 1919.

DR. JOHN A. MCCAW, Presiding.

Corneal and Uveal Tuberculosis.

W. C. BANE, Denver, again presented a case of corneal and uveal tuberculosis exhibited at the previous meeting of the society. At that meeting the tension of the patient's right eye was 54 mm. of mercury, and the tension subsequently increased to about 60 mm. of mercury. On December 31 a scleral puncture was made in the lower outer quadrant, and the tension fell to 20 mm. of mercury; but in three days had risen to 43 mm. of mercury, and in five days to 60 mm. There was also by this time severe pain in the eye. On January 11 sclerocorneal trephining was done, using the Fox flap. After a few hours the eye was comfortable, and there had been no return of pain. The tension was still subnormal; the vision at times of the hand as an object.

DISCUSSION.—J. A. Patterson, Colorado Springs, referred to a case of uveitis in which on account of increase of tension he had done two trephinings, with temporary improvement each time, but permanent gain was apparently interfered with by a large store of whisky which was concealed in the patient's residence.

Edward Jackson, Denver, referred to a case of trephining in which the large cystoid scar of irregular shape persisted after the operation, the trephine opening being visible as a dark circle through the cyst.

D. H. Coover, Denver, who had done about an equal number of trephine operations with the Elliot flap and with the Fox flap, felt that with the Elliot flap one was much more likely to get a cystoid cicatrix than with the heavier flap. He thought that the reason there were so many cases reported of infection after the Elliot operation was that the conjunctiva became so thin that there was more danger of germs penetrating than through the heavier flap. If this flap were seen several months later it would be very much thinner, but it would not be so thin as with the Elliot technic.

C. E. Walker, Denver, referring to the fact that in Dr. Bane's case the use of atropin had apparently greatly increased the tension before operation, suggested that in any case where atropin seemed to be indicated but its use involved some risk, it was better to use homatropin on account of the fact that the action of the latter was much briefer and much more easily controlled.

J. A. Patterson, Colorado Springs. It is often difficult to get sufficient dilatation with homatropin. I inject dionin, holocain, and a drop of the ordinary 4 per cent solution of atropin under the conjunctiva, with excellent results. The dionin greatly hastens complete action of the atropin.

E. R. Neeper, Colorado Springs. We have not sufficiently realized the value of cocain in these cases. I have had much better results from using cocain in conjunction with the mydriatics than where they were used by themselves. By this process adhesions break down much more rapidly. The cycloplegics all cause a relaxation of the circular muscles, whereas cocain contracts the straight muscle fibers.

W. H. Crisp, Denver, stated that he had on several occasions, with great advantage to the patient, changed from the use of eserin to that of atropin, after satisfactorily testing the patient's reaction to the use of homatropin.

J. A. Patterson, Colorado Springs. In the case of an eye struck by a ricocheted bullet, where the patient was uncomfortable under either atropin or eserin, the eye became quiet and comfortable under the use of a prescription containing a small amount of cocain a small amount of holocain, and some hyoscin.

Dr. Bane (closing). The opinion was freely expressed at the last meeting that trephining would be undesirable in my case; but the operation has so far proved beneficial and has not given rise to any trouble whatever.

Iridectomy for Glaucoma; Communicating Vein on Disc.

Edward Jackson, Denver, showed a man of 65 years upon both of whose eyes an iridectomy had been done for glaucoma by Dr. E. V. L. Brown of Chicago. Before the operation vision had been failing rapidly, and each disc was cupped 5 or 6 diopters. Now, eight months after the operation, the eyes were quiet, tension right 28 and left 20 mm., and vision was improving slightly (right vision of moving objects, left 2-100ths). In the left eye a communicating vein, as large as the superior and inferior branches, formed an irregular circle two-thirds the diameter of the disc, starting from the superior vein close to where it emerged, passing around the temporal side of the glaucoma cup, and ending in the inferior branch. It was quite tortuous, and seemed to give off no small branches in its course.

Discussion.—W. H. Crisp, Denver, had seen this man several times before he went to Chicago for his operation, the last time being about two weeks before the operation. At the first visit, the tension had been right 45, left 55 mm.; which after two instillations of eserin 1 to 360 had fallen to right 32, left 42; the vision of the left eye at the same time rising from 2/15ths mostly to 5/8ths partly. The patient was irregular in his use of eserin and in his attendance at the office; and although warned that an operation would be necessary to save vision, insisted on postponing action. The last that was heard of him was that he was going to a Chicago surgeon at the expense of the Pullman Company, whose employee he was.

Optic Neuritis.

Dr. W. C. Bane again presented the case of neuroretinitis in a woman of 54 years which was exhibited at the previous meeting. The vision of the affected left eye was on the previous occasion nil. Vision began to return in this eye on December 28, the first evidence being ability to see flashes of light. The vision was now 1/240th. The disc was slightly pale yet some of the nutrient vessels were present. The patient had been taking 1/30th of a grain of strychnin three times daily, and the high frequency current had been used about every third day.

Discussion.—E. R. Neeper, Colorado Springs, suggested that if the disc had been growing whiter during the past month and the vision had at the same time shown improvement, further improvement was fairly likely.

D. H. Coover, Denver, recalled a case which he had exhibited some years previously, of a little Jewish girl who had a retrobulbar neuritis apparently due to ethmoid inflammation. Immediately after the ethmoids were opened and free bleeding began the vision started to improve. In this case the improvement of vision was coincident with whitening of the discs.

Edward Jackson, Denver. As a rule, in retrobulbar neuritis the disc is left somewhat white, and you cannot tell from the disc what the vision is. The majority of these cases show some whitening of the nerve head even with full vision.

Magnet Extraction of Steel.

William F. Matson, Denver, presented a man of 52 years whose left eye was penetrated on August 15, 1918, by a chip of steel from the drive rod of an engine. The fragment, 0.5 by 5 mm., passed through the cornea and iris midway between the pupil and the sclero-corneal margin. There was very slight hemorrhage in the anterior chamber and no opacity developed in the lens. The foreign body, which was shown by X-ray to lie on the floor of the eye in the vitreous, was removed through a scleral opening between the external and inferior recti muscles, by means of a small tip which was attached to Dr. C. E. Walker's giant magnet. With a plus 2.25 cylinder axis 30 degrees the patient had 20-20ths vision in this eye. The other eye had

been blind since boyhood from traumatic cataract. The eye was kept thoroughly under control with atropin for six weeks after the injury.

Discussion.—C. E. Walker, Denver. The decision to enter through the sclera posterior to the ciliary region was due to the fact that there was no opacification of the lens. After separating a small flap of conjunctiva, the sclera was punctured with a Graefe knife. The small tips which can be applied to the giant magnet make it equally if not more efficient than the hand magnet.

W. C. Bane, Denver, referred to a recent case in which from the X-ray it was uncertain whether the foreign body was within the back of the eye or not, and the giant and hand magnets both failed to move the foreign body. But, it being necessary to enucleate the eye on account of extreme mutilation, the foreign body was found to be embedded in the sclera.

E. R. Neeper, Colorado Springs, had had several cases in which the eye had gone to the bad later, sometimes several years after the removal of a foreign body with seemingly perfect results. On the other hand, he recalled a case in which a piece of bottle glass had passed through the vitreous and made its exit at the temporal edge of the disc, and yet the eye had healed without incident, and vision was as good as that of the other eye.

F. E. Wallace, Pueblo, had seen a case in which a piece of steel was embedded just above the optic disc, but the outcome had justified a waiting policy. The danger zone of the eye had not been injured.

Proliferating Retinitis (?), Dating from Infancy.

Edward Jackson and C. O. Eigler, Denver, presented a case, in a girl aged 12 years, of fundus disturbance dating from infancy. Along the lower temporal vessels of the right eye there was a white area and nearby some small black pigment spots. Some white streaks connected the white area with the vessels. The principal area was perhaps in advance of the level of the retina. The condition was apparently an old one, and the etiology was questionable. From the streaks on the vessels and the apparent connection of these with the white area, Dr. Jackson was disposed to think that it had originated in a hemorrhage, possibly a hemorrhage at birth. The fact that some of the streaks ran up to the disc suggested that the case might be reckoned as one of proliferating retinitis.

Secretary.

OPHTHALMOLOGICAL SECTION.

Baltimore City Medical Society.

Meeting of January 22nd, 1919, held by invitation at General Hospital, No. 7, Evergreen Junior.

Dr. J. W. Downey, Jr., Presiding.

In the absence of Colonel Bordley, Major Ardan gave a talk, briefly going into the history of the founding and development of the Hospital and School for the reeducation of the blind.

The patients after being admitted are given a physical examination by the different members of the staff to determine their suitability for hospital training, and are then put to school work. The course is divided into four periods of two months each.

When the patients enter they are, as a rule, very much depressed, and for the first period are given a large amount of entertainment and physical exercise in the recreation building, with a short period of manual training in weaving and other arts which develop their tactile sensation. An interesting fact is that those men who have been used to manual work, and therefore have thickened cuticle on their finger tips are more apt than those who have less hardened epidermis.

In the second period the hand work is continued, the recreation and entertainment is lessened with instruction in vocational training, which varies with the aptitude of the individual. The third period is arranged with still more vocational work and less amount

of entertainment and recreation, while the fourth period consists largely of specialized vocational work.

In this course the man is not alone taught how to use his hands, but is also taught how to conduct a business for himself, and, as a rule, a man's near relative, either sister, brother or fiancee is invited to the instructions and receives training along with the soldier: so that on leaving the school they will be in a position to support the scholar both morally and in a business way. The hand work being taught thruout the four periods.

Lieutenant Campbell showed several very interesting cases that had returned from the front; consisting of gas cases, cases for plastic work, simple chronic glaucoma in a boy of twenty-one, and a case of conical cornea; after which a tour of inspection was made of the buildings and the work accomplished.

Mr. Campbell, assistant director of the institution, then gave a very instructive discourse upon the advanced methods used in the teaching of the blind, after which the meeting adjourned.

Secretary.

ABSTRACTS

Koster, W.—Removal of Small Foreign Bodies from the Anterior Chamber.—Tidjdschr. v. Geneesk. 1917, v. 1, p. 802.

Every ophthalmologist with experience will agree that the removal of foreign bodies from the anterior chamber is not easy. Even when the foreign body is of iron or steel, its removal may be difficult. The surgeon who does not proceed systematically may not succeed at all, and the eye be lost.

Bodies larger than 2 mg. of iron or steel give the least difficulty. One attempts removal with the giant magnet thru the opening in cornea or sclera, if the trauma is recent. In each case the presence and the location of the piece has been determined with the sideroscope. Mostly, however, the corneal wound is small and closed, so that the anterior chamber has reformed. The particle brought thru the pupil with the magnet, strikes the cornea, often against the closed wound, thru which it passes if presenting its shortest diameter. These are the easy cases.

It is not so easy, if the splinter is very fine and the wound already closed, as happens with very small corneal traumas. Then a new opening must be made at the periphery of the chamber, where the piece drops, when the magnet stops attracting it. The particle is entirely invisible, being behind the limbus. One must now enter the anterior chamber, as peripherally as possible, where one knows the particle to be, with a fine Graefe knife directed radially, and then make an incision along the corneal margin, a little longer than the foreign body, or at least to 6 mm. With the pole of the hand magnet the scleral side of the wound is pressed slightly, when the foreign body presents itself.

The mistake mostly made is that the incision is too much in the cornea, or that the opening is made with the triangular keratome, at the place where the particle is. The piece of metal lies then in the chamber angle, behind the scleral wound lip, and is held by the iris tissue as soon as the aqueous has escaped. And even a strong magnet is incapable, with the pole in the wound, to extract it, as it becomes pressed in the iris tissue. If one tries to move the particle the next day, when the chamber has reformed, one will not succeed as exudate will fix it in the root of the iris.

If Koster has to treat failed extractions, he locates the splinter with the sideroscope as accurately as possible; and at that spot he makes a scleral angular incision with one line in the limbus and the other radial in the sclera. The chamber angle, with the root of the iris and ciliary body is then ex-

posed, the point of the flap is pulled outward with a fine sharp hook, and the giant magnet brings forward the particle. One incision along the limbus is insufficient. The flap is replaced with a superficial suture.

Too little attention is paid to the minuteness of the attractive force of the strongest magnet on the very small particles. When the anterior chamber is absent they are easily retained by folds of iris. It is not advisable with a very fine splinter kept against the back of the cornea by the magnet, to perforate the cornea at that place with a bistoury, which the magnet does not attract. These knives are never very sharp; and those small splinters move so often in the anterior chamber that they can be at another place, when the paracentesis has been done. They cannot then be moved and one must wait some hours until the chamber is restored.

Nonmagnetic bodies are mostly lead shot, or pieces of copper, more rarely pieces of glass and stone, a few times pieces of reed or wood. The Roentgenogram is of the first importance for the diagnosis of lead or copper in the chamber angle. Pieces of glass remain mostly in the neighborhood of the cornea, penetrating or hung on it. Thru explosion of glass vessels glass can go deep in the eye. If a piece of the glass is at hand it should be examined for its penetration by Roentgen rays. A glass splinter in the anterior chamber is often seen better than expected thru the totally reflecting borders at the planes of fractures.

One should not try to remove such foreign bodies thru a straight line wounds, and no surgical forceps should be used. A good access must be made toward the foreign body by lengthening if necessary, the wound opening, so that a flap is formed, which can be lifted with a sharp hook. It is preferable to make in the cornea a fresh incision at right angles, with a Graefe knife alone or with a pair of blunt, strong scissors. If necessary a third incision is made, so that a square flap is formed, the base of which is made, if possible, toward the limbus. If the foreign body is thus well exposed it should be grasped with a strong anatomic forceps. One or two fine superficial silk sutures may be used, or, if necessary, cover with a conjunctival flap.

In an eye, where the original wound has well closed, the keratome can be used sometimes, but with the narrow knife the chance is greater for the incision to be perpendicular thru the cornea, which gives more room, and a contact can be more easily prevented with the knife than with the keratome. For foreign bodies in the chamber angle first a radial incision next the object is made, as peripherally as possible, with the sharp edge of the knife outward; and the cut along the limbus with blunt scissors in the direction of the body. Or one plunges the knife first at one side of the object peripherally in the limbus, goes around first at one side of the object and comes out at its other side again thru the limbus. After an incision is thus made thru the limbus, one makes with scissors at one or both ends radial incisions in the cornea, and lifts this flap firmly with a sharp hook. The hemorrhage is here of no consequence. If, however, one enters with iris forceps thru a keratome incision, and while the iris lies against the cornea, wishes to grasp with surgical teeth a hooky or globe-like object, a hemorrhage will start and obscure sight of the object. If one keeps on trying, the foreign body moves the deeper.

Koster describes a case where, after a failure in extraction, he succeeded. Enucleations should not be hastily resorted to. Thru explosion a piece of glass entered the anterior chamber, lying at the temporal side of the iris. The glass was partly in the pupillary space. The next morning the piece was below in the anterior chamber. The ophthalmologist made an incision below with the keratome, and tried to grasp the glass with iris forceps. Hemorrhage started, and after some vain trials the foreign body could not be seen. Two days later the patient came under Koster's care. There was still some blood there, and the pupil was

filled with opaque lens substance. However, a parallelogram-shaped piece of glass, probably 3 to 5 mm., was seen lying in the pupillary space, with tension a little too low.

Next morning, at the upper margin of the pupil, somewhat to the nasal side, an incision 8 mm. long was made perpendicularly thru the cornea, with a very fine Graefe knife. With curved tenotomy scissors a second incision 6 mm. long was made toward the nose downward in the cornea perpendicular to the first. The angle of these two was lifted with a very fine sharp hook; the lens substance with the foreign body and also a bead of vitreous pushed a little into the opening. Koster was able to grasp the piece of glass with strong, fine anatomic forceps. Lens substance was partly removed. The wound closed well. No sutures in the cornea. Conjunctiva a little loosened nasally and upward, and after pushing it over the end of the corneal wound it was sutured. Slight compressive bandage and bed rest. Two years later the eye can be corrected to vision of nearly 6/6.

E. E. B.

Stephenson, Sydney.—Orbital Suppuration from Acute Anterior Ethmoiditis in Young Subjects. (British Journal of Ophthalmology, Aug. 1918, p. 416.)

The writer has found the form of orbital suppuration described in this communication tolerably common in young children, altho the essential nature of the condition is not always recognized. It is not rare to see a young child suffering from general malaise with swelling of the lids of one eye, which is more or less prominent, in which orbital suppuration is unrecognized. Many of the milder cases get well under simple treatment, or without treatment, with or without a discharge of pus from the nostrils, or into the nasopharynx.

But a certain number of the cases return later with signs of so-called "orbital cellulitis" or "orbital suppuration"; presenting tenderness, edema, redness, chemosis, protrusion, downward or downward and outward, and impaired motility of the eyeball, together with general symptoms such as malaise, elevation of temperature, headache and vomiting. The condition is always unilateral, and there is an absence of history of coryza.

Stephenson is convinced, from his clinical observations, that these cases deserve to be classed as a separate entity, and that they are explained by an acute inflammation of the anterior ethmoidal cells (in severe cases inflammation of the posterior ethmoidal cells can not be excluded). The condition is not accompanied by any ophthalmoscopic signs, is not followed by optic nerve atrophy; and these patients do not die from intracranial complications.

Many get well under the simplest treatment—a cathartic, and locally a continuous dressing of six per cent alcohol or hot applications of boric acid. When symptoms are severe, or the general condition of the patient is threatening, surgical measures must be adopted.

The usual procedure is to make an incision into the orbit over any spot which seems to indicate the presence of underlying pus. If nothing escapes, the dressing forceps, with closed blades, are introduced into the depths of the wound, and the blades of the instruments are then separated more or less widely. In some instances of this operative procedure there is no escape of pus until two or three days later.

Several experiences of this sort led the writer to adopt a somewhat different procedure. Under general anesthesia, a curved incision down to the bone was made over the inner angle of the orbit extending from the root of the nose to the inner end of the eyebrow; a small raspatory was then introduced beneath the periosteum over the region of the anterior ethmoidal cells and pus usually escaped. Or, if the simpler orbital incision is preferred, in the absence of distant indications to the contrary, it is advised that the opening be made over the region of the anterior ethmoidal cells. The paper concludes with details of ten cases selected from a larger number.

DISEASES OF THE EYE DURING THE CIVIL WAR.

As the time has arrived for collecting material for and the actual writing of the Medical and Surgical History of American participation in the Great War, it is of interest to ophthalmologists to inquire into the subject of ocular affections as they drew the attention of military surgeons during our Civil War. Practically the only record is that preserved in the third medical volume of the impressive Medical and Surgical History dealing with the medico-military activities of 1861-1865.

The section "Diseases of the Eye" was made a separate order of "Local Diseases, Order II," instead of being included with "Diseases of the Nervous System," as was done by Farr, the British statistician.

In this classification were included amaurosis; cataract; inflammation of the iris; night blindness; ophthalmia; inflammation of the retina; other diseases of this order; inflammation of the conjunctiva; not a very elaborate or distinctive list, surely, but one, nevertheless, that mirrored ophthalmic knowledge (or the lack of it) in the early sixties.

In Medical Volume III, p. 849, we are told, under "Ophthalmia," the inflammations of the eye were reported prior to January 30, 1862, under the headings *Ophthalmia* and *Iritis;* subsequent to that date the term *Conjunctivitis* was substituted for the former.

During the five and one-sixth years covered by the medico-military service, 8,904 cases of ophthalmia and 65,739 of conjunctivitis were reported among white troops, making a total of 74,643 cases. Included among these were probably many cases of corneal infection, as 1,463 cases—1.96 per cent. of the whole number, or one out of every fifty-one cases—were discharged as unfit for military service; the average annual sick-rate being 33.4 cases per thousand men.

These inflammations of the eye were somewhat less frequent among the colored troops, the whole number having amounted to 5,153 cases, or to an average annual rate of 28.1 per thousand. This exceptional infrequency of disease among colored troops is explained by two considerations: "ophthalmia" was not occasioned in a notable degree by the ordinary exposures to cold and wet incident to camp life and active service; but was the

result of special causative conditions existing in certain localities, perhaps trachoma, of which the negro is wonderfully free. Moreover, these localities were held by a larger proportion of white than of black troops.

Ophthalmia prevailed to a much greater extent among the troops serving on the Gulf Coast than among those operating against Richmond. During the year ending June 30, 1865, 1,198 cases of conjunctivitis were reported among the 80,982 white troops constituting the Army of the Potomac, while 2,158 cases are said to have occurred among the 45,629 white soldiers serving in the Department of the Gulf. The prevalence in the latter area was attributed to sunglare, to dust and to sandy particles in the air of stations on the coast line. Colored troops operated in this department, but the majority of those that contributed to the statistics held the line of the Mississippi River and were protected from the exposure to which the ophthalmia was attributed.

The record further shows that during the four years, July 1, 1861, to June 30, 1865, the average annual rate of prevalence of ophthalmia among white troops was, in the Army of the Potomac, 17.5 per thousand strength, in the Department of the Gulf 37.0, in the Department of New Mexico 47.5, and in the Department of the Northwest 85.0—the rate for the whole army having been, as already stated, 33.4 per thousand. In the northwest the glare from snow was regarded as an etiologic factor, taking the place of the sand-glare of other regions.

It was also contended that the persistence of ophthalmia in individual cases occasionally depended on a rheumatic or a syphilitic taint. Its prevalence or persistence in a command was sometimes ascribed to influences affecting the constitution. These were generally malarial; and as proof it was noted that some of the worse cases were cured in a short time after resorting to quinin. Eye inflammations that prevailed in two Ohio regiments were attributed to the existence of the scorbutic taint.

No specific mention was made of trachoma, nor of any form of contagious conjunctivitis, as such.

It is easy to point out that the Civil War History furnished the most meager and insufficient accounts of those ophthalmic diseases that prevailed during the war period, and in view of the probability that they did not much differ from those encountered by medical officers during the present war, is additional evidence of the ineffectiveness of the service from the ophthalmic standpoint.

On the other hand, when one considers that modern ophthalmic surgery was then only in its infancy, that definite information regarding the eye diseases was not accessible or nonexistent, the explanation is easy. Let us hope that the History now in preparation will deal completely with all the phases of military ophthalmology and compare favorably with the reports on the other branches of war medicine and surgery.

C. A. W.

A WORLD CONGRESS OF OPHTHALMOLOGY.

When war was forced on Europe in August, 1914, it immediately destroyed any possibility of the Twelfth International Ophthalmological Congress which was arranged to meet in "St. Petersburg" on the 14th of that month. Some of the papers to be presented to the Congress were already printed, and American Ophthalmologists, some of whom had already entered Russia and other countries that were first precipitated into war, will remember their experiences in escaping from the war zone as among the most strenuous and alarming of their lives.

The world has traveled far since 1914; new nations and new issues have risen, and the dream of permanent peace has drawn to the study of its problems the rulers, diplomats, and even the military authorities of the world. In the future international channels of communication and international gatherings must assume an importance greater than they ever had before; and among these channels of communication scientific journals and scientific congresses should show a most striking development.

It will be ten years in April since the Eleventh International Ophthalmological Congress met in Naples. Fully another

year must elapse before the arrangements for another such gathering can be completed. It is high time that a movement looking to preparation for it should be started. At the Naples meeting the United States was the chief rival of Russia as a claimant for the privilege of entertaining the Ophthalmologists of the world; and now Russia is impossible for such a gathering and must be so for years to come.

In the welter of world war, revolution and anarchy, the members of the local committee who organized for the Twelfth International Congress have disappeared, probably many of them are dead.

The initiative for a new gathering must come from a new source. Because of the terrific strain to which the leading civilizations of Europe have been subjected, the United States of America is by far the best place for the assembling and entertaining of such a Congress in the early future. We suggest that at the national meetings to be held in Atlantic City in June the necessary committees be formed to extend the invitation for such a Congress.

Some one of the Eastern cities that has been proved a good meeting place for our national medical organizations should be chosen for the holding of the Congress. It is nearer than London or Paris, not only for the United States, Canada, the West Indies, and Latin America, but also for Australia, Asia, and Japan; and equally near for South Africa.

When the Tenth International Ophthalmological Congress met in Lucerne, the majority of those who were contributing to the science and literature of ophthalmology lived within five hundred miles of that place; and few beyond a thousand miles except in the Eastern United States. Now, with important centers of scientific activity in Argentina, Egypt, India, Australia, and Japan, we have a whole round world to consider in choosing a meeting place. On the surface of a sphere one point is as near the center as another.

In planning for such a World Congress, certain departures should be made from the plans that have been followed in the past. In the first place, the Congress should meet once in three years. But few would attend each successive Congress although there have been American ophthalmologists who planned to spend each summer vacation in Europe. The majority of those attending any particular meeting will be residents of the quarter of the globe in which it is held.

The Congress will not reach its full usefulness and development unless the opportunity for such attendance is afforded the ophthalmic workers in all quarters of the globe. If the opportunity is to come once in ten years to North Americans, or once in twenty years to India or Australia, meetings must be held more frequently. The few who travel widely will want at least a few opportunities to visit remote portions of the globe.

In a series of gatherings each composed largely of a different personnel, there is need for a more permanent executive body or organization. This must almost of necessity be based on the different national organizations of Ophthalmologists. Representatives from each of these can constitute the business commission of the Congress; by which the local committees for arrangements can be named and the publication of the transactions and such matters provided for.

Such a Congress, working along broad lines, can do much to secure a general hearing for scientific observations relating to ophthalmology wherever these be made. Its influence would be felt not only thru its own transactions; but still more thru a more general acquaintance with the persons and publications concerned with ophthalmic science and art thruout the world. E. J.

BOOK NOTICES.

MIRRORS, PRISMS, AND LENSES. A Text-book of Geometrical Optics. By **James P. C. Southall**, Associate Professor of Physics, Columbia University, New York. 8vo, 600 pages, 247 illustrations. New York. The Macmillan Co.

For the ophthalmologist who seeks a really broad educational foundation in optics, this work will be of interest and value. Thoro fundamental training in optics is too often neglected in preparation for ophthalmic practice; and the text-books that would help to give it, published in English, have been few and not always well written. Even for the student of ophthalmology who may never master it; a careful inspection of what this book contains will furnish a broader view of what the optical study for his specialty should imply.

The work is divided into fifteen chapters, and the reading of the headings of these gives an idea of the extent of the subject. They are: Lights and Shadows; Reflection of Light; Plane Mirrors; Refraction of Light; Refraction at a Plane Surface and also thru a Plate with Plane Parallel Faces; Refraction thru a Prism; Reflection and Refraction of Paraxial Rays at a Spherical Surface; Refraction of Paraxial Rays thru an Infinitely Thin Lens; Change of Curvature of the Wave-front in Reflection and Refraction. Dioptry System; Astigmatic Lenses; Geometrical Theory of the Symmetrical Optical Instrument; Compound Systems. Thick Lenses and Combinations of Lenses and Mirrors; Aperture and Field of Optical System; Optical System of the Eye. Magnifying Power of Optical Instruments; Dispersion and Achromatism, and Rays of Finite Slope; Spherical Aberration, Astigmatism of Oblique Bundles, etc.

The reflection of light which takes up the second chapter is mathematically simple as compared with refraction; and forms an excellent introduction to the more complex phenomena of the latter. It is too much neglected in works written for medical students and practitioners. The chapter and sections here devoted to it, could be read with interest by one who knows little of elementary mathematics.

With regard to the chapters on refraction it is different. Altho this work by its large number of diagrams properly emphasizes the geometric side of optics, there are many algebraic formulas in it, the development of which requires close study even from one who has made himself familiar with the symbols used, and sets himself carefully and seriously to working out these formulas.

A notable feature are the problems appended to each chapter. By these the reader or student, who takes up the study without an instructor, can test his progress, or the thoroness of his grasp of the principles and methods he is studying. Some of these problems have quite a practical bearing on ophthalmic optics.

For the teacher of advanced optics, or the writer who wishes to get a broad view of this subject, this book will be highly valued as a book of reference. It appears to have been carefully prepared and proof-read for the elimination of errors. The diagrams are well proportioned and for the most part clearly lettered. It will be found the more suggestive because it is written from a point of view different from that of the practicing ophthalmologist. E. J.

TEXT-BOOK OF OPHTHALMOLOGY. By **Ernest Fuchs** and **Alexander Duane.** Fifth Edition. Octavo. 1067 pages, with 462 illustrations. Philadelphia and London. J. B. Lippincott Co.

The American Edition of Fuch's monumental work is described by Alexander Duane, the American editor, as "In several senses a new work." Yes, we may say it is a new work, and it may be perhaps permitted to say that the modesty of the American editor has been somewhat stretched in calling himself the translator. Really the work has been written by Fuchs and Duane, the former furnishing the skeleton and the latter the body and the habiliments. Some of the subjects have been so elaborated, or the manner of discussion has been so changed, that it were difficult indeed to ascribe the ideas to the Viennese author.

This fifth edition is very little like those which have appeared in the German language; if it were not for the old familiar illustrations it would be hard to recognize this as Fuch's text-book, then too, the illustrations have been amplified. Recent changes from the former American editions are in particular the chapters of Glaucoma, The Retina, Disturbances of Motility, and the sections on Refraction and Operations. Many of the newer methods, descriptions and even theories are included in this fifth edition, "Largely made on the editor's own responsibility."

The familiar appeal to the general practitioner in the preface is hardly applicable. Neither this nor any of the editions of the work were ever quite adapted to the common variety of doctor, or even to the beginner in ophthalmology. This is a book that is of primary use to the practicing ophthalmologist, and to him largely as a store house of information. The beginner would be appalled by the vastness of the subject and even by the size of the book, which now reaches one thousand and sixty-seven pages. He should first read text-books of less pretensions.

The reviewer's advice to the progressive oculist is, to buy this edition and shelve the older ones. H. V. W.

TRANSACTIONS OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY. Volume 16. Fifty-fourth Annual Meeting, 1918. 8vo, 412 pages, 23 ils., 1 col. plate, 19 other plates. Published by the Society, Thomas B. Holloway, Secretary, Philadelphia.

This volume contains the papers, discussions, and proceedings of the last annual meeting of the society, with sketches of two of its deceased members; and the candidates' theses of the nine associate members elected at the annual meeting.

The latter occupy over 160 pages; and add greatly to the scientific value of the volume. They abundantly justify the practice of requiring candidates to show their ability to contribute to the proceedings of the society. The requirement that they should do so has stimulated the production of some valuable papers. Some of these have already been published in this journal; and others will be brought before our readers in subsequent issues.

The volume is better illustrated than its predecessors. There are 23 cuts and diagrams in the text, and 19 insert plates and one in colors. The introduction of illustrations adds substantially to the value of almost any clinical report. It is a poor picture, indeed, that does not tell more about a clinical case than the text that would occupy an equal space. But there is as much to be learned of expression thru pictures, as of expression thru phrases and sentences.

Again the reader is urged to have these transactions in his library if possible. The early volumes may not be obtainable, but the current volumes can readily be procured thru the Secretary of the Society. E. J.

CORRESPONDENCE.

MUSCLE OPERATIONS.

To the Editor:—

Allow me to send you a few reflections suggested by the two letters dealing with operations for squint, in the November number of the AMERICAN JOURNAL OF OPHTHALMOLOGY, pp. 806-807.

A discussion between two medical men is never a disagreement between two persons, but between two opinions; a third person may therefore intervene, especially if he hopes to demonstrate that the divergence originates merely in an insufficient precision of the words used, and that the two colleagues are not speaking exactly of the same thing.

In the present case the word that lacks precision is "operation." If Dr. Loeb had written: "The position that all cases of convergent strabismus should be *tenotomised* is not a tenable one," I am certain that Dr. O'Connor would have been entirely satisfied. He might perhaps even have emphasized on the sentence, saying —as I say myself, after such personal experience I may have gained, and especially after all I have seen of my father's work for so many years—"The position that hardly any case of convergent strabismus should be tenotomised, is the only tenable." If, on the contrary, Dr. Loeb was speaking of advancement,

our two colleagues agree again, since Dr. O'Connor writes: "Few of us who operate, do so until we have eliminated the cases that are cured by glasses and visual training."

In fact, I doubt that this latter was the meaning of the word operation in Dr. Loeb's mind, for he would not have said that some operations result in strabismus of the opposite character, this being an inconvenience special to tenotomy.

Dr. Loeb advocates the nonoperative treatment, which gives him 40% correct positions of the eyes: the percentage is very good and does much credit to the author's skill and patience. He will, however, admit that the difficulty increases with the degree of the squint and the amblyopia of the deviated eye. Again, the amblyopia gets worse as time passes away, and the contractility of the externi gets weaker and weaker; this is a fact well known to any one who takes the trouble of measuring the excursion of the eyes.

If, then, a method—be it an operative one—enables us to reduce considerably the angle of squint, and, on the other hand, if by increasing the power of the externi, without impairing the strength of the interni, it gives the eyes a far better mobility, without any risk of divergent squint, there is no doubt that in the hands of so skillful an orthoptist as Dr. Loeb, such a method may give a still better percentage of correct positions. It may additionally enable to secure binocular vision, even if that has not been asked for, and, with the patient satisfy also the oculist.

The muscular advancement is the method I mean. With all its advantages it may be performed on very young children, when the amblyopia is not inveterate and the chances of subsequently restoring binocular vision are the very best possible.

Of course, there is no question of operating all cases before having thoroly tried the nonoperative treatment; in case of failure it is the best preparation to the postoperative training of the binocular vision.

In short, I believe that if in the pending discussion the word operation means tenotomy, Dr. O'Connor will agree with Dr. Loeb, and if it means advancement, Dr. Loeb cannot but agree with Dr. O'Connor.

Begging both our colleagues pardon for my intervention—our readers for my hesitating English—I am,

Respectfully yours,

Dr. Marc Landolt.

Paris, France.

OPHTHALMIC JURISPRUDENCE.

By Thomas Hall Shastid, M.D., LL.B.

SUPERIOR, WIS.

Recent Law Decisions of Special Interest to Ophthalmologists.

People v. Griffith. (Supreme Court of Illinois, June 21, 1917, 117 N. W., 195.) A. B. Griffith, convicted in the Municipal Court of Chicago of practicing optometry without a license, brought the record by writ of error to the Supreme Court. The essential question involved was whether or not the Optometry Act of Illinois was valid, i. e., constitutional. *Held:* It was not. The judgment was therefore reversed. Reasons: (1) The act exempted from examination those who had practiced three years, entirely regardless of moral character, temperate habits, age, skill, knowledge, or competency to practice optometry. (2) It prescribed no subjects for examination.

The importance of this decision is very great.

Martin v. Commonwealth. (Supreme Court of Appeals of Virginia, Sept. 20, 1917, 93 S. E. 623.) J. Harry Martin, convicted of practicing medicine in the City of Roanoke, Va., without first having procured a certificate from the Board of Medical Examiners of Virginia, brought a writ of error to the Supreme Court of Appeals of Virginia. Dr. Martin was a nonitinerant optician, who displayed on the front door and window of his place of business the following legends, "Dr. J. Harry Martin, Incorporated, Eyes Exclusively" and "Dr. J. Harry Martin, Incorporated, Optometrist." The conviction was had on section 12 of the Medical Practice Act of Virginia, which runs as follows: "Any person shall be regarded as practicing medicine within the meaning of this act

. . . who shall use in connection with his name the words or letters 'Dr.,' 'Doctor,' 'Professor,' 'M. D.,' or 'Healer,'" etc. But the judgment was reversed on the strength of section 11 of the same act, which exempts "any noniterant person or manufacturer who mechanically fits or sells lenses, artificial eyes . . . or is engaged in the mechanical examination of eyes for the purpose of adjusting spectacles, eye-glasses or lenses."

Routt v. Brotherhood of Railroad Trainmen. (Supreme Court of Nebraska, Nov. 3, 1917; 165 N. W., 141.) The plaintiff sued the Brotherhood in the District Court of Douglas Co., Nebraska, on a benefit certificate held in the defendant company, Rule 68 of the company having provided that "Any beneficiary member in good standing who shall . . . suffer the complete and permanent loss of sight of both eyes, shall be considered totally and permanently disabled and shall thereby be entitled to receive . . . the full amount of his beneficiary certificate." The plaintiff had become unable to distinguish the colors red and green. The vision for no other color was affected, and the visual acuity remained substantially unchanged. Judgment below was given for plaintiff, and defendant company appealed to the Supreme Court. There the judgment was affirmed. the court declaring that "Complete and permanent loss of the sight of both eyes means loss of the use of the sight of both eyes for the purposes of the insured's avocation."

The opinion is plainly in accordance with prior law (e. g., Kan. v. C. B. & Q. Ry. Co., 90 Neb., 1112, v. B .R. T., 75 Neb. 183, and of Sneck v. Traveller's Insurance Co., 88 Hun, 94) but a strong dissenting opinion appears in this case.

Fring v. Pierce-Arrow Motor Car Co. (169 N. Y. Supp., 309.) *Held*, in this case, that the loss of the lens of an eye is not the "loss of an eye." True the loss of coordination of the two images prevents the simultaneous employment of both eyes, but, still, the injured eye would be a reserve of sight in case of an accident to, or the destruction of, the other eye. [Cf. Magnus and Wurdemann's "Visual Economics," Wurdemann's "Injuries of the Eye," and "Legal Relations of Ophthalmology" in "Am. Enc. of Oph.," p. 7042.]

Beardsley v. Ewing et al. (Supreme Court of North Dakota, Aug. 10, 1918, 168 N. W., 791.) From the viewpoint of a physician, one of the most important cases ever decided in this country. In fact no doctor, either general practitioner or specialist, can read this newly decided case without a feeling of intense dismay.

The facts are as follows: The plaintiff, a railway engineer, got a cinder in one of his eyes on Dec. 19, 1914. After various ineffectual attempts to remove the cinder himself, he went on the following morning (Dec. 20) to the offices of the defendants. There the cinder was removed. No bandage was applied, but the plaintiff was offered a prescription for a solution of boric acid—which, however, he refused. On Dec. 21, this time with a very painful eye, he went once more to the offices of the Drs. Ewing. On this occasion a bandage was applied, and a prescription was given for an argyrol solution. On the day following, Dec. 22, the plaintiff appeared once more at the offices of the defendants, this time with a well developed ulcer, and then (only two days after his first appearance in these offices) was referred to the head eye surgeon of the Soo Ry. Co. in Minneapolis, Dr. George E. Benson. An operation was performed by Dr. Benson, the eye was saved but the sight was lost.

At the trial, eight expert medical witnesses declared, under oath as a matter of course, that the treatment of the eye, as given by the Drs. Ewing, was absolutely all that could be desired. As far as the official records show, there was little or nothing in the testimony of Dr. Benson, who had been subpoenaed by the plaintiff, on which a judgment for the plaintiff could rationally be based. Moreover, the plaintiff and his wife were permitted to testify "to the size of the abscess on the eye on the 22nd of December. Certain improper questions were also asked of one of the defendants, on cross-examination, as follows: (1) Whether or not said defendant was insured against loss in malpractice cases, (2) whether or

not his brother, the other defendant in the case, was similarly insured. A witness, Dr. Grogan, was also asked (1) whether or not his expenses were met by the Northwestern Medical Association, (2) whether or not counsel for defendants were employed by the Northwestern Medical Association. An alleged improper suggestion was "made by plaintiff's wherein he said that 'the manner in which these physicians stand together is disgraceful.'"

Judgment was given for the plaintiff in the sum of $7,933.50.

Defendants appealed to the Supreme Court, which, however, sustained the judgment, holding (1) a question of negligence is one of fact for the determination of the jury, (2) a layman is competent to testify to the size of an abscess which can be observed with the naked eye. [The fact that a layman would not know an abscess from a bit of tenacious mucus is not adverted to. A layman would, in fact not know whether an abscess of one size or another was or was not present.] (3) The improper questions asked and improper suggestions made by the counsel for the plaintiff, are not reversible errors.

Once more the writer can only observe that any doctor, whether a general practitioner or a specialist in ophthalmology, can only read the decision in the case of Beardsley v. Ewing et al. with consternation and dismay. Howsoever right the treatment by a given doctor in a given case may be, and howsoever numerous and trustworthy may be the expert witnesses who testify in his behalf, and howsoever slight the testimony may be which is given against his treatment, the doctor, as it seems, may yet be mulcted in heavy damages. There is, however, a single dissenting opinion in this report, that of Justice Robinson, which exhibits a perfect comprehension of the case in its medical, as well as its legal, aspects. The justice, at the close of his opinion, in fact declared: "Clearly the judgment should be reversed, and the action dismissed, because from the record it appears that there can be no evidence to sustain a verdict for the plaintiff."

NEWS ITEMS

DEATHS.

Dr. Clarence John Blake, Boston, aged seventy-five, died at his home, January 29th. Dr. Blake was so close to the ophthalmologist by virtue of his allied specialty that we note with deep regret that he has passed away.

Dr. Thomas Buzzard, of London, died January 1st, aged 88 years.

Dr. William F. Mittendorf, who began the practice of ophthalmology in New York City more than thirty years ago, died on February 14th, 1919, in his seventy-fourth year, and was buried in Sleepy Hollow Cemetery at Tarrytown.

Dr. Richard A. Reeve, Professor of Ophthalmology and Dean of the Medical Faculty of the University of Toronto, and Ex-President of the British Medical Association, died suddenly in Toronto, Canada, on January 27th, aged 77 years.

Dr. Abraham Sachs, of San Antonio, Texas, died January 19th.

MILITARY.

Capt. H. K. Fleckenstein, of Baltimore, is now at the head of the service at Camp Meade.

Capt. Charles P. Small, of Chicago, has been sent to take charge of the Post Hospital at the Rock Island, Illinois, Arsenal, U. S. Army.

Lieut.-Col. Greenwood and Lieut.-Col. Derby have just returned from long service overseas. It is reported that they will both soon be discharged from service.

Major A. C. Magruder and Capt. E. M. Marbourg of Colorado Springs have been honorably discharged from the service and have resumed their practices at home. Major Magruder saw almost eighteen months of service, a large part of which was as Commanding Officer of the base hospital at Fort Sill.

Lieut.-Col. George E. de Schweinitz of Philadelphia presided at a recent meeting, which was held in the American Academy of Music, upon which occasion Sir Arthur Pearson of St. Dunstan's, London, made a most illuminating address upon the education of the blind soldier. Col. de Schweinitz preceded the address by some appropriate reference to Sir Arthur's work, based upon his recent visit to St. Dunstan's.

Lieut.-Col. Casey A. Wood is spending a few months at Stanford University, California. No

doubt he is working up something that he will give us later on. He has recently addressed the "Twilight Club" of Pasadena on "Problems Connected with the Reconstruction of Disabled Soldiers."

George E. de Schweinitz, Lieut.-Col. M. C., U. S. A., Philadelphia, has been appointed general consultant in ophthalmic surgery to the Surgeon General of the Army; Col. Vilray Blair, consultant in oral and plastic surgery; Lieut.-Col. H. P. Mosher, consultant in otolaryngology, and Major Charles H. Frazier, consultant in neurosurgery.

Honorable discharge from service in the U. S. Army has been granted to Doctors A. L. Benedict, of Buffalo, T. A. Woodruff, of Chicago, H. W. Loeb, of St. Louis, J. O. McReynolds, of Dallas, Texas, W. B. Lancaster, of Boston, Mass., E. S. Sherman, Newark, N. J.

Capt. A. B. Middleton, M. C., of Pontiac, Ill., who has had charge of the Base Hospital Eye Dept., and served as Oculist for the Special Medical Board for the past year at Camp Travis, Texas, was discharged, and returned home March first.

Sir Arthur Pearson, the blind founder and director of St. Dunstan's Hotel for Blinded Soldiers, London, addressed a mass meeting at the Century Theater in New York City on February 4th. He described his work in restoring blinded British soldiers to self-support. Lieut.-Col. James Bordley, who is in charge of work for blinded American Soldiers and Sailors, and Director of the Red Cross Institute for the Blind, told of the work being done at Evergreen, Baltimore, for the men of the American Expeditionary Force who lost their sight in action.

PERSONAL.

Dr. John A. Donovan has been elected President of the Chamber of Commerce of Butte, Montana.

Dr. Daniel W. White, of Tulsa, Oklahoma, was married on the 19th of February to Miss Connor Trotter, of Kansas City.

Dr. R. L. Randolph, of Baltimore, Md., has resumed his practice after a month's needed rest.

Dr. Wm. T. Shoemaker, who has just returned from France, has been elected Chairman of the Ophthalmologic Section of the College of Physicians of Philadelphia.

Dr. and Mrs. L. Webster Fox announce the marriage of their daughter Celia to Mr. Charles Francis Griffith, on Thursday, February the twenty-seventh, 1919.

Dr. Clarence E. Ide, honorably discharged from the Medical Corps of the U. S. Army, has resumed the practice of his specialty at San Diego, California, in the offices formerly occupied by the late Dr. W. Williamson.

Dr. J. A. Hughes, having completed the combined Eye, Ear, Nose and Throat internship at Brooklyn Eye and Ear Hospital, announces his association with Drs. Hill, Howard and Fagin, Suite 930, Exchange Building, Memphis, Tenn.

Dr. Harry Friedenwald, of Baltimore, has left for a six months' sojourn in Palestine, as Medical Advisor for the Sanitary Commission, and also to bring a report from the Medical Department of the Jewish University at Jerusalem.

Dr. Samuel D. Risley, of Philadelphia, has been the recipient of many congratulations upon his having recently passed another milestone of life's journey in greatly improved health, notwithstanding the exactions of a very active private practice.

The President of the College of Physicians of Philadelphia has appointed the following members of the Ophthalmic Section as the Executive Committee: Dr. Samuel D. Risley, Dr. S. Louis Zeigler and Dr. Thomas B. Holloway.

Dr. Sterling G. Ryerson, founder and past president of the Canadian Red Cross Society, has resumed practice in Toronto after four years' work in France and England, and various parts of the American Continent in the interests of the Canadian and American Red Cross Societies.

SOCIETY NOTES.

The Medical Society of the State of California will meet in Santa Barbara on April 15, 16, 17. The Eye, Ear, Nose and Throat Section is preparing a very attractive program.

Dr. G. Oram Ring was recently elected President of the Philadelphia Medical Club, and Dr. Wm. M. Sweet one of the directors. The club now numbers about eleven hundred physicians in its membership.

Dr. L. Webster Fox of Philadelphia, President of the Pennsylvania Home Teaching Society and Free Circulating Library for the Blind, made an appropriate introductory address preceding a lecture by Dr. George Earle Raiguel, upon "What England, France and Italy are Doing for the Blinded Soldier; America's Opportunity," which was held in the Rose Garden of the Bellevue Stratford Hotel, on Wednesday evening, February 5th.

At a meeting of the College of Physicians of Philadelphia, on February 5th, the scientific portion of the meeting was devoted to papers on "Concussion and Injuries of the Eye in Warfare," by Lieut.-Col. George E. de Schweinitz; "Reeducation of the Blind" by Lieut.-Col. James Bordley; "Research Work on the Problems of Aviation" by Major Walter B. Lancaster, and the "Army School of Ophthalmology" by Major Meyer Wiener.

At the meeting of the New York Academy of Medicine, Section on Ophthalmology, January 19th, papers were read by Dr. W. M. Sweet, of Philadelphia, on "Implantation of a Gold Ball"; Capt. Harvey J. Howard, of Boston, "Implantation of a Glass Ball," and Dr. A. N. Alling, of New Haven, Conn., on "Implantation of Fat." Mr. Pierre Gougelmann gave a paper from the standpoint of the artificial eye maker. At its meeting on February 17th, Dr. E. Torok gave the paper of the evening on "Tuberculin in the Diagnosis and

Treatment of Eye Diseases," with a report of twelve years' experience. This paper was discussed from the standpoint of the general practitioner and of the oculist.

On the 8th of November the opening meeting of the Irish Ophthalmological Society was held in Dublin, after the Montgomery Lecture by Dr. Euphen Maxwell, Mr. James Craig, Belfast, in the chair. The rules were drawn up and adopted, and the following were elected to hold office for the ensuing year:—President, Mr. A. W. Sandford Cook; Council, Messrs. J. B. Story, L. Werner, J. A. Craig, H. C. Mooney, F. H. Crawley; Hon. Sec. and Treasurer, Lt.-Col. T. H. Delany, I. M. S. (retd.).

Mr. Werner exhibited lantern slides of a case of cysticercus, published in the *Transactions of the Ophthalmological Society of the U. K.* (Vol. 23, p. 193), and Mr. Story charts of Fields of Vision in Glaucoma. On the following day patients were shown at the Royal Victoria Eye and Ear Hospital, among others a patient whose case was published in the *Transactions of the Ophthalmological Society*, 1891, page 127, of detachment of the choroid; also two cases of fat implantation, one in Tenon's capsule, and the other in the sclerotic after evisceration, the eye in each case being buphthalmic.

MISCELLANEOUS.

By the will of Mrs. Ada B. B. Dixon the sum of $1,500 is bequeathed to the Presbyterian Eye, Ear, Nose and Throat Hospital, Baltimore, as a tribute to the memory of Dr. John Dixon.

A Joint Influenza Committee has just been created to study the epidemic and to make comparable, so far as possible, the influenza data gathered by the Government Departments at Washington, D. C.

The Ophthalmic Hospital of St. John in Jerusalem, the only one of its class in Palestine, and used by the Turks as an ammunition store and partly destroyed by them on their retreat, now appeals for assistance to rebuild. The sum hoped for is 50,000 pounds, to maintain and extend the work.

In the "Paris Letter" to the A. M. A. Journal, there is a report of Dr. F. de Lapersonne on the results obtained since July 15th in the treatment of eye injuries. Eighty-three cases were operated upon. In all but three the operation was performed under procain anesthesia, irrespective of the extent or degree of the intervention. When radiography showed the presence of a foreign body, or of a fracture, he frequently resorted to orbitotomy, making a curved incision (following the rim of bone), which gave free access to the orbit, at the same time insuring the safety of the conjunctiva and the palpebral fissure. He insists that immediate suture of wounds should be the absolute rule in these cases of orbito-ocular wounds which come under the head of urgent surgery.

Harris Turner, M. L. A., will be provincial representative for Saskatchewan for the Canadian National Institute for the Blind. C. W. Holmes, director of the Canadian National Institute, and himself a blind man, recently visited Saskatoon and spent some time with Mr. Turner discussing plans for extending work for the blind in this province. Mr. Holmes purposes, with the approval of the executive committee, to establish at least one home teaching circle in each province. A competitive teacher is to be in charge, who shall not only act in the capacity expressly understood by the term, but also as a local paid representative under the immediate direction of the local member of the Western committee, which will be a center of information and activity. Mr. Holmes said that the plan outlined was the only practicable one to advance rapidly. That such a plan, carried out, would enable him to accomplish more in one year, at less expense, than he could single handed, or even with a competent central staff, in five years. For several years past Mr. Holmes has been in Massachusetts in connection with educational work for the blind. When the institute was established in Toronto, he was called to Canada to take charge of it.

OPHTHALMIC LITERATURE

These lists contain the titles of all papers bearing on Ophthalmology received within the preceeding month. These titles are all in English, some of them modified to indicate more clearly their subjects. These subjects are grouped under appropriate heads, the succession of groups being the same from month to month. In the group the papers are arranged alphabetically usually by the name of the author in heavy-face type. After the subject of the paper (Ill.) indicates the number of illustrations. (Pl.) the number of plates, and (Col. pl.) colored plates illustrating the article. (Abst.) shows that it is an abstract of the original article. (Bibl.) tells that the paper is accompanied by an important bibliography. (Dis.) means that a discussion of the subject is published with it. Under Repeated Titles are indicated additional publication of papers already noticed. To secure the earliest possible notice writers may send copies of their papers, or reprints, to 318 Majestic Bldg., Denver, Colorado.

CLINICAL NOTES ON VERNAL CATARRH OR EXUBERANT PERICORNEAL CONJUNCTIVITIS

DR. JOSE DE JESUS GONZALEZ,

LEON, GTO, MEXICO.

This paper calls attention to ametropia and keratoconus consecutive to this disease; the value of the x-rays in its therapeutics, reports a case of large recurring vegetation invading the cornea and cured by the x-rays. It was presented to the Section on Ophthalmology of the Fifth National Medical Congress of Mexico, held in Puebla, January, 1918.

Although the literature about exuberant pericorneal conjunctivitis, so named by Dr. Manuel Carmona y Valle, is very extensive, there remain to be explained some points about its complications, therapeutics and atypical forms. Therefore, the clinical notes here given are important.

I. *Keratoconus of rapid development consecutive to exuberant pericorneal conjunctivitis.*

For many years I have insisted that vernal conjunctivitis develops an irregular astigmatism in eyes emmetropic before being affected by such conjunctivitis.

In the second annual meeting of the Mexican Ophthalmic Society in 1905,[1] and later in the third meeting of the same society,[2] I presented some observations on patients with vernal catarrh whom I had the opportunity to observe from the beginning of their affection and for several years thereafter. In all these cases, free from ametropia in the beginning, I saw a compound irregular myopic astigmatism develop, with the exception of a single case in which the astigmatism was hypermetropic.

Convinced that my patients were emmetropes from the onset of their vernal catarrh and having seen not only the appearance of ametropia, but its increase in a short time (up to 2 diopters in three years, in one case), naturally I attributed the change to the vernal catarrh, for these three reasons: First, the conjunctival disease appears in the eyes of children, eyes in the course of development; second, the nutritive modifications which the pericorneal infiltration must bring to the cornea; and, third and very important, because of the mechanical influence of the pressure and friction thru the closed eyelids, which the little patients constantly rub with their fingers, in order to calm the most persistent subjective symptom and annoyance of the disease, the itching.

In one or another meeting of the ophthalmic society my observations seem to have been received with a certain skepticism, as one could see in the minutes published in their reports.

Now I bring the new observation made on a young girl affected with vernal catarrh, in whom I have seen appear and develop in two years a decided keratoconus. This observation is highly demonstrative that the vernal catarrh has etiologic influence in producing the malformations of the cornea which cause ametropia and corroborates my previous observations, giving undeniable proof of the view I have sustained for several years.

Case I.—Miss R. S., at present twenty years of age, of Conguripo (State

of Michoacán), presented herself for the first time in my ophthalmo-neurologic office in 1913, then sixteen years old, for treatment of an ocular affection which began two years previously. Careful examination showed me that she suffered from a bulbar form of the exuberant pericorneal conjunctivitis, without participation of the tarsal conjunctiva, with opalescent infiltration of the limbus towards the superior portion and big pericorneal nodules in one or both extremities of the horizontal meridian, in the uncovered parts of the conjunctiva. The characteristic subjective symptom of this disease—the itching—was intense. As usual, the patient showed alternately improvement in the winter months and exacerbations in the hot months; but as the climate in which the patient lives is hot, the improvements in winter were slight.

On refracting her, I found both eyes completely emmetropic, with sharp visual acuity equal to normal. I treated the patient for several weeks and after that she went to her home.

In 1916 she returned to my office, and what was my surprise in finding in both eyes an enormous keratoconus, perfectly transparent, and with the vision below one-twentieth. Of course, the vernal catarrh has not disappeared.

Looking at one or the other eye in profile, a glance brought to notice the accentuated conical form of the cornea. Examining the superficial transparent membranes with the keratoscopic disc of Placido, it showed a characteristic malformation of the concentric circles.

The anterior chamber was deep. Iris, refractive media and the ocular fundi, normal. Vision R. 1/25; L. 1/50.

Refraction: Irregular myopic astigmatism. The skiascopic examination showed at once the annular shadow, concentric at the pupillary border, with its center illuminated—a shadow which is almost characteristic of keratoconus, altho it is observed also in lenticonus. On rotating the reflecting mirror the annular shadow showed irregular movements and deformaties. In causing the patient to look in different directions, in order to retinoscope the peripheral parts of the cornea, we observed the two luminous bands which had the scissors movement as it appears in irregular astigmatism.

The refraction of the extreme meridians was the following: R. oblique meridian 25°. —9D; meridian at 90°. —13D. L. oblique meridian at 160°. —9D, oblique meridian at 80°. —15D. The correcting lenses hardly improved the vision for distance. Also the visual acuity for reading distance was notably decreased.

What is interesting in this case is the complete absence of any hereditary record (I have examined her parents, her maternal grandmother and some uncles, and none of them presented any errors of refraction) as well as the rapidity with which the keratoconus developed.

Did this vernal conjunctivitis cause the keratoconus? We do not apply the post hoc ergo propter hoc principle, but we must reflect on all this detail: 1st the absence of any other cause; 2nd the previous affection, with its intense pericorneal infiltration, naturally produced nutritive modifications in the cornea, which decreased its resistance to the intraocular pressure; and 3rd the continued frictions and rubbing practiced on the cornea through the closed eyelids, in order to relieve the itching, mechanically flattening the transparent membrane, must also modify its elasticity.

The ignorance in which we still are about the real pathogenesis of keratoconus, does not permit us to estimate the influence of each one of these causes, considered separately; but surely, united, they have not been foreign to the production of the bilateral keratoconus in our patient.

In speaking of the prognosis of vernal conjunctivitis, one must take into account the possibility that in time it may produce astigmatism, that would diminish the vision of the patient. It is customary in my office to study the refraction of all patients who have been suffering several years from vernal catarrh. This has caused me to observe the emmetropia at the beginning of the illness and to later discover the

ametropia, almost always myopic astigmatism.

When the patient does not present any error of refraction, I am so convinced that the vernal conjunctivitis can cause it, that I always advise the patients of this possibility, in order that they may be warned.

We can see that if, exceptionally, the vernal conjunctivitis produces corneal alterations able to disturb its transparency, it is not so rare that it produces modifications in the curvature of this transparent membrane, which always decreases the visual acuity.

X-rays and the therapeutics of exuberant pericorneal conjunctivitis.

Is the use of the X-rays in the treatment of the periodic vegetative conjunctivitis, as Dr. Antonelli calls it, rational?

The question must be cleared a priori by considering the pathologic histology of the affection, and the special action of the X-rays; and a posteriori, by observing the results obtained in the clinic.

The most notable in the histologic lesions of the vernal catarrh is the proliferation of the epithelial cells, accompanied by a proliferation of the subepithelial tissue, the epithelial hypertrophy predominating in the bulbar regions, and the conjunctival proliferation in the tarsus (Taylor and Danvers). The European histologists and our Mexican histologists are in accord on this point. According to Dr. Antonelli[3], the epithelium is not very much changed, but very much thickened. There exists an infiltration of small cells which constitute a granulomatous focus of leucocytes. There are numerous spaces and cystic cavities of three species: cysts of vacuity by degeneration of the epithelial cells; small lymphatic cysts; and, at last, isolated cavities well formed in the fibrous stroma. Antonelli believes that vernal catarrh is a chronic inflammatory process of the conjunctiva, which terminates in vegetations without it being possible to know the cause.

In some cases, the leucocytic infiltration is so abundant that it has caused Michel to think that the primary lesion is a lymphoid nodule.

Our histologist Dr. M. Toussaint[4], had said: "In short, the alterations consist of the epithelium being thickened in some places and thinned in others, and infiltrated by leucocytes, to a point that the subepithelial tissue presents the aspect of an abundantly vascularized infectious granuloma. Before Dr. Antonelli, Dr. Toussaint had already mentioned the existence of holes or vacuoles, some of these occupied by small migratory cells.

Another of our histologists, Dr. Ricardo Cicero (in the thesis of Dr. Chavez, already mentioned), divides the lesions into superficial epithelial ones, and lesions of the subepithelial layers. In the first he finds an active epithelial proliferation with a mucous degeneration of the cells; as to the subepithelial layer it has a texture similar to the infectious granuloma, there is an agglomeration of embryonic cells, tightly packed among themselves, and some of these acquire fusiform shape and have serous infiltration, the cavities are fairly abundant and some fibers of conjunctival tissue cross between the epithelial cells. We see, therefore, that there are numerous young cells of new formation, and, at times, lymphoid nodules.

"The X-rays act principally on the lymphoid system and on the young tissues of new formation."[5] From all that precedes we can a priori affirm that the X-rays must have a beneficial influence in the exuberant pericorneal conjunctivitis; as its indication is based on two scientific data of the greatest importance; the histologic nature of the vegetations, and the special action of X-rays on new formations of that nature.

Now let us see what the clinic says a posteriori. All my patients with vernal catarrh whose history I will briefly mention, have been treated by the Roentgen therapy in the office of Dr. Cornelio Larios, of the city of Leon.

The tube employed is focussed with an automatic vacuum regulator; there is always used a protective screen and a localizing diaphragm, in order to

limit the action of the X-rays to the desired part. The quality of the X-rays that we have used is from 6 to 7 of Benoist radiochromometer.

The quantity is estimated by the calorimetric apparatus or radiometer of Sabouraud-Noiré, composed of screens of platino-cyanide of barium. It never reaches the quantity of 5 H. We are therefore, very far from having ocular lesions, above all in the retina and the optic nerve, as observed by Birch-Hirschfeld in those cases in which the eye has been exposed to the radiations of 25 units of Holzknecht.

The precautions taken are so much more necessary because the patients frequently are children whose eyes, in course of development are more susceptible to the action of the X-rays, than the eyes of adults, according to the investigations of Tribondeau and Belley, mentioned by Dr. Leprince[6] of Bourges.

The duration of the exposure never lasts more than 8 minutes, the eyes are kept open, and the upper eyelid is inverted when it is a tarsal case, although this detail is not indispensable. Frequently repeated exposures have never been needed. As a general rule they have been practiced every three weeks or at longer intervals.

During the first days which follow each exposure to X-rays the patient does not feel any inconvenience. But two or three days after, as it were following a period of incubation, one observes an exacerbation of all the symptoms of vernal catarrh. The vascular injection of the conjunctiva is more intense, the vegetations increase in volume and a slight mucous secretion appears, even in cases which did not present it before. There is a sensation of foreign bodies in the conjunctiva, the itching increases, and in a very few cases, there exists a slight photophobia. This exacerbation lasts a few days, without opaqueness of the cornea or iritic phenomena, or fundus lesions, or the slightest diminution of visual acuity, or any symptoms of radiodermatitis. At the end of fifteen days, all has come to its old condition, and, from that moment, begins regression of the lesions of the limbus and tarsus. If after three weeks or one month the improvement has not been very marked, a new exposure of the eyes is made to Roentgen radiation.

This method of procedure differs from that which has been in use by others, such as Casey Wood[7] of Chicago, who mentions the case of a little girl afflicted in one eye only with vernal catarrh of the tarsal variety, whose affected parts were exposed daily, during six weeks to the action of the X-rays.

On the other hand, this method is similar to the manner in which Drs. Davidson and Lawson[8] have applied the radiations of radium in a case of vernal catarrh. They practiced the treatment during one year, and, in this time each eye was subjected to eight radiations, without ever observing any accidents or without obtaining a complete cure. In order to appreciate the therapeutic result it is necessary to recall the evolution of vernal catarrh in our country. The unfavorable influence of heat on the affection which we are studying being unquestionable, in countries where the seasons are more marked, so are the periods of exacerbation and improvement, the first coinciding with the spring—hence its name—and the second with winter. All of our Mexican oculists are in accord with that, in our country the course of the disease varies a little, owing to our special climatic conditions.

The patients whom I observe all live —with few exceptions—on the Central Plateau, which is located between 1,000 and 2,000 meters above sea level, whose climate is temperate and whose winters are not very severe. The disease follows this course: It is chronic, lasts several years—I have seen it lasting from the age of twelve to the age of twenty-six; it begins with childhood—I have seen it even in children four years of age; it generally attenuates with age and disappears in adolescence. Once it has appeared it simply shows variations of aggravation and improvement, without completely disappearing during the winter. The exacerbation begins in February, accentuates in March and April and keeps

its intensity during May, June, July, August and September. It begins to improve in October and the improvement reaches its apex in December and January.

Improvement in spring or summer and complete disappearance in winter is exceptional. I have observed it in patients with X-rays. However, I do not speak of cure except when they have passed one or two years without a relapse in spring and summer. This is the view of Doctors Zentmayer, Wood and Carpenter[9].

Here briefly are some of my most important observations.

Case 1:—A. M. twelve years of age from Lagos de Moreno, State of Jalisco, a city of temperate climate. He has been suffering for years from an ocular affection for which he came the 18th of March, 1916, as his disease began to show an exacerbation. I found him affected with vernal catarrh, of the bulbar and tarsal variety, with large pericorneal nodules, and abundant tarsal vegetations. There was hardly any secretion, but he suffered intense itching. I always obtain improvement with the following treatment: two drops twice daily of a 5 per cent solution of argyrol, and two drops of this formula: sterilized water 10 grams, solution of 1:1000 of adrenalin 1 gram, hydrochloride of cocain 0.05 centigrams; ointment of Verges of yellow oxide, 2 per cent every two or three days; and daily steaming with Laurenzo's vaporizator.

I prescribed all of this, and the treatment was followed for some days; but as he could not remain in the city, he asked me for some means to alleviate his sufferings as soon as possible. I used the X-rays. An eight minute exposure was made, following the precautions already indicated; after four or five days of incubation the reaction of which I spoke appeared, which got better at the end of two weeks. The patient returned to his residence and I advised him to use only the argyrol and the cocain-adrenalin solutions.

On the following 28th of April he again presented himself much improved. The pericorneal nodules had almost disappeared and the tarsal exuberances greatly diminished. At the limbus persisted, that whitish enlargement toward the upper part of the cornea so well described by Uribe Troncoso[10] and which is for me one of the symptoms which help me most in establishing the diagnosis. The itching had improved. I must call the attention to this improvement, observed in full spring, when in previous years it was the most painful time for the patient. After a new application of X-rays he returned home where he followed the previous treatment.

On the 18th of June he consulted me again. There was complete disappearance of the tarsal exuberances in the left eye, hardly perceptible in the right eye; disappearance of the limbal inflammation and of the pericorneal nodules; the itching has almost disappeared. Owing to this evident improvement no application of X-rays was made and the previous treatment was continued. On the twelfth of August, the tarsal conjunctivas were smooth, there remained only a slight vascularization in spots very limited in both eyes, about where the pericorneal vegetations existed; no itching. From that date, and during the hot months of 1917 the affection did not recur. I cured it in full summer with only two applications of X-rays.

Case 2. Child five years of age, from Lagos de Moreno (Jalisco), bulbar form of vernal catarrh; limbal inflammation toward the upper part, and pericorneal nodules in the part uncovered by the lids. Nothing in the tarsal conjunctiva. He consulted me in March, 1915. As the affection was recent, I thought that the case was a favorable one for the application of X-rays; and a five-minute exposure was made on each eye. After three or four days of incubation, the symptoms of radio-conjunctivitis appeared, but not very intense. They lasted ten days. They attenuated immediately, and then began the improvement of all symptoms of vernal catarrh; which disappeared completely in two months, in full

spring, after a single application of X-rays, and with only the aid of argyrol and the instillations of cocain-adrenalin.

The year 1916 passed well, but at the end of February, 1917, the patient was brought to me again with some tarsal conjunctivitis; slight thickening of the conjunctiva towards the external side of the horizontal diameter, in both eyes; a small nodule of exuberant perikeratitic conjunctivitis in the right eye. After new applications of X-rays, the phenomena of reaction were of small intensity during the first fifteen days. Then there was progressive improvement of the affection, until cure in full spring. He passed the summer well and continues well.

Case 3: Miss R. S. 20 years of age of Conguripo (Michoaean), a warm climate.

This is the same girl in whom developed keratoconus. Application of X-rays in May, 1916; reactionary phenomena intense, with mucous secretion, slight photophobia, marked hyperemia of the conjunctivas, and engorgement of the vegetations. With daily vaporizations with Laurenzo's apparatus and instillations of the cocain-adrenalin solution, the reaction disappeared in fifteen days, and the improvement began. Cessation of the itching, disappearance of the secretion and of the photophobia; marked lessening of the hyperemia and of the pericorneal vegetations. After a month, new application of the X-ray; less intense reactionary phenomena followed by marked improvement in spite of the hottest days in July. Unfortunately I have not seen the patient again, as she returned to the place of her residence, rather distant, and altho she wrote me that she continued being better, I cannot give any more details. The miotics and the compresses have been the remedies employed for the keratoconus.

Cases 4, 5 and 6: Three cases of the tarsal variety, without participation of the bulbar conjunctiva. Mr. A. H. 25 years of age of Oxetlan, Jalisco (temperate climate). Mrs. A. H. 30 years of age of Aguas Calientes, and Mrs. H. R. 23 years of age, of Aguas Calientes. These three suffered for years exclusively from the tarsal form of vernal catarrh, with very voluminous vegetations limited to the tarsus, without participation either of the transitional folds or of the bulbar conjunctiva. The itching in all was intense, and in none of them was there any secretion. They presented themselves during the hot months of the year. Each one underwent, with intervals of one month, two exposures—the lids being inverted—to the radiations of Roentgen. The reactionary phenomena were not intense and the improvement evident. The subjective symptoms of itching, and the volume of the tarsal exuberances notably diminished in full summer.

As a year has not yet passed, we can not consider the cure definite; but it is to be noted that none have heretofore felt such great improvement.

These observations, especially the first two, show that Oram Ring[11] was right in asserting that the X-rays have an evident therapeutic value in vernal catarrh.

III. *Very large recurrent vegetation which invaded the cornea and yielded to the X-rays.*

The exaggerated development of tarsal vegetations in exuberant conjunctivitis has been observed several times. I had the opportunity to observe in a young person, 16 years of age, a very interesting case, in which, besides the numerous small pavementlike vegetations, like the pavement of the street, existed in each upper lid, three or four vegetations of enormous development, up to ½ cm. long, and with a base of narrow implantation: I had to extirpate them for the inconvenience they caused the patient.

Another interesting case in a girl, 14 years of age, was presented by our distinguished oculist, Dr. Daniel Velez,[12] under the name giant papillomas of the tarsal conjunctiva in vernal catarrh. The histologic examination of one of these papillomas, made by Dr. M. Toussaint, showed the peripheral layer formed by a stratified pavement-like epithelium, with numerous swollen cells, some of these cells are vesicular

and among them there are migrating cells. The rest of the small tumor consists of a very vascular fasciculated tissue, and among large agglomerations of cells, some small ones, without much protoplasm and with nuclei rich in coloring matter, others are large with an abundance of protoplasm and consisting of two types: plasma cells of Unna and granular cells of Ehrlich. The histology of these tarsal vegetations is identical with that of the other lesions of vernal catarrh. In spite of my bibliographic investigation, I have not found a case similar to that which I am going to describe, as when the cornea has been invaded to some extent, no vegetation has taken an exaggerated development.

Case 7. The boy, age 13 years, of Aguas Calientes, was brought by his father to my office in April, 1911, in order to have a small tumor, developed in the left eye, attended to. The eye had been operated on three times; once in Aguas Calientes, by an oculist who visited the city, whose name he did not know; another time in San Luis Potosi, by the well known oculist Dr. Antonio Alonso, and the last time in Mexico, by the distinguished ophthalmologist Dr. Fernando Lopez, who applied the galvanocautery. In each case the tumor recurred in a few months, acquiring a large volume.

Examining the young boy I discovered what one observes in the oil painting which I took from nature, see plate VII. In the right eye is a bluish-white infiltration of the corneal limbus, toward the external part, a diffused, vascularized enlargement of the conjunctiva to a large extent around the limbus; and vegetations of the tarsal conjunctiva, separated by well marked furrows. The fornix and the inferior palpebral conjunctiva were normal. There was a slight mucous secretion. It is to be remembered that it was in the month of April—and there was a very accentuated itching.

In the left eye the tarsal manifestations were similar to those of the right eye. In the bulbar conjuctiva there existed, towards the internal angle a large diffused vegetation; and on the cornea another large hemispheric vegetation of the size of a split pea, of a reddish yellow color, and obstructing already almost half of the pupillary field. One could notice also in the cornea a whitish cicatrix, linear, vertical, almost tangent to the small tumor, a trace of the operation practiced in Mexico by means of the galvanocautery.

According to the father of the patient, the affection was of two or three years' standing, and was getting worse during the hot months of the year. The clinical diagnosis was unmistakable; it was a case of exuberant perikeratitic conjunctivitis in its tarsal and bulbar forms, and one of the vegetations had come to a considerable development, invading the cornea, and seriously affecting the vision.

The prognosis was not encouraging; the recurrence of the large corneal vegetation, in spite of the well known ability of the operators, left me doubtful, and obliged me to look for positive therapeutics to remedy the condition.

I proposed to the father of the patient, and he accepted, to make a fourth extirpation of the enormous corneal vegetation, in order to see if it were possible to avoid recurrences which were making the case desperate; and then we would apply X-rays.

This was done. During the operation the vascularization of the tumor was ascertained, and as the adhesion to the membrana propria of the cornea was very pronounced, it was necessary to leave a thin layer of the vegetation. A five-minute exposure to the Roentgen rays was made, exclusively localized to the left eye.

As the reactionary phenomena were not very marked, we continued exposing the eye during five minutes every fifteen days for two months, at the end of which time we suspended them, because the radiometer of Sabouraud had indicated the limit of absorption.

As the recurrence of the corneal vegetation was generally evident at the end of two months, and at this time it had not yet appeared, I began to hope that the recurrence would not again reappear. However, the father of the

patient and I, being watchful, did not let the boy go home for four months, with the injunction to present himself each month, for the application of other radiations. Effectively they were applied twice more. I have observed the patient for years. Since 1911 I have not lost sight of him, and in more than six years there has not only been no recurrence of the tumor, but all the conjunctival lesions have disappeared in the left eye, there remaining only an intense opacity of the cornea in the former site of the vegetations, and the vertical cicatrix of the galvanocautery.

A very interesting detail which converts this case into real proof of experimentation is: As the young boy and his father were afraid that the X-rays might have a bad effect on the retina—as some suggested to them—they wanted me to expose only the eye with the tumor, whose vision was already affected, and to not touch the right eye, which it was necessary to protect specially. The tarsal and bulbar lesions of this side did not improve equally with those of the other. They continued with the summer and spring exacerbations of bad to worse, and winter improvements. Submitted to cocain-adrenalin and argyrol, the tarsal and pericorneal lesions improved gradually, perhaps rather on account of the spontaneous tendency that the disease has to improve.

A final detail: The left eye now presents a mixed astigmatism, horizontal meridian +4 D., vertical meridian —1 D.

The visual acuity is R. = 1. L. without optical correction = 0.5.

For purposes of comparison I remember some twenty-five cases of exuberant perikeratitic conjunctivitis, not treated by X-rays; which followed the course that we all know, some lasting fourteen years, others disappearing at the end of 3, 4, or 8 years.

I now attend a little girl of Lagos de Moreno, aged 8 years, who for two years has been suffering from exuberant conjunctivitis, and each year, in the warm months, comes to me for attendance; her father has not permitted the application of X-rays; and the yellow oxid of mercury, vaporization cocain-adrenalin and argyrol, have on her a beneficial effect, but without curing her.

VERNAL CONJUNCTIVITIS IN CUBA.

Dr. Juan Santos Fernandez.

HAVANA, CUBA.

Attention is here called to the unappreciated frequency of vernal conjunctivitis, and illustrative cases are given to prove its identity altho its course is modified by special climatic conditions.

The cases of spring catarrh seen in Cuba, like those of trachoma, do not always show the same typical signs of the disease as are seen elsewhere, and as they are not frequent, the diagnosis is not easy, and the disease can be mistaken for other conjunctival diseases including trachoma.

Most of the authors agree that this disease is rarely seen after the age of twenty, but the most typical case we have seen was in a woman of 40 years. The disease attacks by preference males. This we have verified here, but not its dependence on the climatic conditions that elsewhere seem to have such an influence that the disease is called by the name of vernal conjunctivitis. This can be explained by the fact that in Cuba we have summer almost all the time, with the exception of a few weeks of moderately cool (not cold), weather.

Both eyes are usually affected, and there are photophobia, itching, and catarrhal symptoms without mucus. The tarsal conjunctiva presents a whitish, milky, lardaceous aspect. The disease was mentioned by Arlt in 1846, and well described by him in 1851. He believed the transparent, gelatinous infiltration of the conjunctiva, near the limbus, to be a lymphatic manifestation. We remember that the same impression was made upon us when we saw our first case in Cuba; and we thought that with the growing up of the young patient the disease would disappear, but it was not so.

Saemisch gave to the disease the name of vernal conjunctivitis on account of its tendency to recur in the spring of the year; and to be almost well in the beginning of the cold weather. In Cuba, as we said, the disease is not modified in those months. The disease has been called in Mexico, exuberant circumcorneal conjunctivitis. The author that studied it there was Dr. Carmona Valle, and he found the chief symptoms in the bulbar conjunctiva.

The duration of the disease can not be stated, but Saemisch has seen 23 successive attacks in a case during one year. Most of the cases are soon persuaded of the benignity of the disease, and the long treatment wearies them, and they abstain from further treatment.

The frequency of the disease varies. Danvers at Parma had 50 cases among 22,398 patients; Schoebel, at Prague, had 23 cases in 20,000 patients; Schiess-Gemuseus, of Basle, had 14 cases among 28,338 patients; Emmert, of Berne, in 12,486 patients had 48 cases; Knus, from Zurich, in 33,609 patients, saw 64 cases, and Kubli, of Petrograd, among 20,690 patients, only 2 cases. In Cuba, in 61,000 patients we have seen only six cases of the disease.

According to the statistics, the most frequent month is May, but in our cases the months of January, February and April are more frequent. All our cases were from the city, and none from the country. We have not been able to prove any contagiousness, nor have we found any possible bacterial agent as the cause.

All the different treatments used to combat the various affections of the conjunctiva are without good results, when employed in this disease. Today the use of radium is recommended and it shall be employed in one of our cases, and we hope with good results.

We remember the discussion held in the Ophthalmological Section of the A. M. A. in May, 1903, by Drs. Posey, from Philadelphia; Weeks, from New

York; Gradle, from Chicago; Zentmayer, Baker, Woods, Stevenson, Stricker, Gifford, Claiborne, Randolph and others; and in spite of the different opinions, the impression was that there is no recognized etiology, and that all treatments were of no avail.

Three years previously, in March, 1901, Dr. Antonelli held the same doubts at the French Ophthalmological Society, concerning the symptoms, etiology and treatment.

As we have said before, the disease has been studied by Montaño, Velez, Chavez, Uribe-Troncoso, Toussaint and others, at a meeting of the Mexican Ophthalmological Society in July, 1904. At that time Dr. Toussaint showed his microscopic researches, which did not prove anything special, and only enforced the opinion that the disease is chiefly recognized by its physical signs; and did not show in Mexico, as in Cuba, a very regular course.

Case I.—A boy, six months old, was brought to us in February 8, 1904, because his mother thought that he had suffered an injury in his right eye with a toy. But it was not so, and his eyes were in a physiologic state. The boy was again brought into our office in September 17, 1906, with a small phlyctenule of the bulbar conjunctiva, and now we believe that it may have been the beginning of the vernal conjunctivitis that he has had later. We saw him for the third time in 1907, and this time he had a purulent discharge, but the laboratory findings did not show any germs, only leucocytes.

In April, 1910, the boy was seen again by us, because his eyes were red, and there were some small raised spots on the bulbar conjunctiva, of red color and asthenic appearance. We did not then think that they were symptoms of vernal conjunctivitis. But now that the case has been so diagnosed abroad, we believe that what we thought was incipient phlyctenular conjunctivitis, was in reality an outbreak of the spring catarrh, which is not very typical in warm countries.

In May, 1913, we took out a foreign body from his right eye and it was seen that the small lumps in the bulbar conjunctiva had disappeared. But there was still the asthenic congestion of the palpebral conjunctiva in both eyes.

The father brought me the boy on the 22nd of February, 1913, because the child had been taken out of school by the medical inspector, who thought that his son had trachoma. Three other boys had been brought to me from the same school and with the same statements; but the subject of this observation had conjunctivas with a different appearance from that of the others, the case not being one of trachoma. The parents wanted very much to have the boy operated. Altho not believing that surgical procedures would be of great advantage, I practiced a rolling of the everted lids. The case, as expected, did not improve.

In March 11, 1913, the conjunctivas presented the same aspect. Asthenopia corrected with 0.75 plus.

January 5, 1914. Eyes the same as before. Upon being asked to certify the condition I do so as follows: The fatty appearance of the conjunctiva is not due to trachoma, and will disappear on change of climate or when the boy grows up.

September, 1917.—On a visit to New York I found the boy there. The boy has since been seen by Dr. Weeks, who diagnosed the case as vernal conjunctivitis; or spring catarrh; and has recommended the use of radium, which in my belief will cure him.

Case II.—M. G. D., a young man, consulted me in April, 1912, and had been sick three months. The left eye is the one affected. The disease began with some red spots on the bulbar conjunctiva. The case looks like one of phlyctenules, but is not so. We made a diagnosis of vernal conjunctivitis and the patient left for his town, and wrote to us some time afterwards, stating that he was better.

Case III.—Mrs. J. G. R., 44 years old, and native of the Canary Islands, has been living 14 years in Cuba. Strange ocular appearance. The conjunctiva of the globe offered a phlyctenular and membranous appearance.

In the left eye there were corneal opacities, almost hiding the pupil.

The patient stated that she had been sick for over twenty years; the disease began at her birth place. The upper eyelids had a membranous character, and we made the diagnosis of vernal catarrh. After a month of treatment the patient left unimproved.

Case IV.—Boy, six years old (W. P. G.), was seen first on July 24, 1912, and came into consultation for a chalazion. After everting the lids, we noticed a fatty or lardaceous infiltration that might have been diagnosed as trachoma by the health officers. We saw him again in 1915 during a trip we made to New York, and he did not complain of his eyes then. On his coming to Havana in 1917, and upon being examined by the health authorities, he was detained and sentenced to be sent back to New York, because a diagnosis of trachoma had been made. The case was entirely similar to case I, diagnosed as spring conjunctivitis at New York. We were able to arrange things, stating that the case was certainly not one of trachoma, and taking charge of the patient. The boy, after 20 months treatment, has not gotten worse, but has certainly not improved greatly, in spite of the severe winter we have passed.

TRACHOMATOUS CHANGES OF THE CARUNCLE.

Kazuo Hiwatari, M. D.

KYOTO, JAPAN.

The histologic changes in the caruncle here reported seem to throw light upon the embryologic origin of this structure.

Altho trachomatous changes affect almost all the external parts of the eye, up to date no communication has been published of its appearance in the caruncle, as far as my knowledge of the literature is concerned. I therefore wish to report herewith such a case, which I was able also to investigate histologically.

The case concerned a woman, age 21 years, with light grade trachomatous scars of both eyes. At the examination I noticed at once that the caruncle of the left eye had been changed to a tumor the size of a rice grain of grayish yellow color. This tumor was extirpated, fixed and hardened in alcohol and cut in horizontal sections embedded in celloidin. As stain I used hematoxylin (Boehmer) — eosin, and Unna—Pappenheim's mixture.

It showed on careful investigation of the sections that the tumor consists of four lymph nodules lying closely together; each nodule is provided with a well developed but not sharply marked germinating center.

They contain also numerous, typical Leber's bodies, such as we always find in the trachoma follicle. About in the center of the tumor, i. e., between two neighboring follicles, we find a deep cone-shaped depression of the epithelium with narrow lumen, which shows the characteristics of a stratified pavement epithelium conforming to the normal structure of the epithelium of the caruncle. In the lumen of this depressed epithelium and between the epithelial cells, one observes many emigrated lymphocytes, histocytes as well as polynuclear leukocytes.

The epithelial covering of the tumor is largely stretched and thinned out, so that the underlying epithelial cells, which normally are high cylindrical, appear here more or less plainly flattened. The goblet-shaped cells which under normal conditions appear here

very often, are absent. Towards the plica semilunaris the subepithelial tissue, which was slightly scarred, is numerously impregnated with plasma cells, histocytes and lymphocytes, and passes without demarcation into the old scar of the plica.

Medially, i. e., towards the inner canthus, the subepithelial tissue appears thru the compression of the tumor more or less dense, without, however, showing a strong cellular infiltration (See ilustration, Fig. 1). Considering

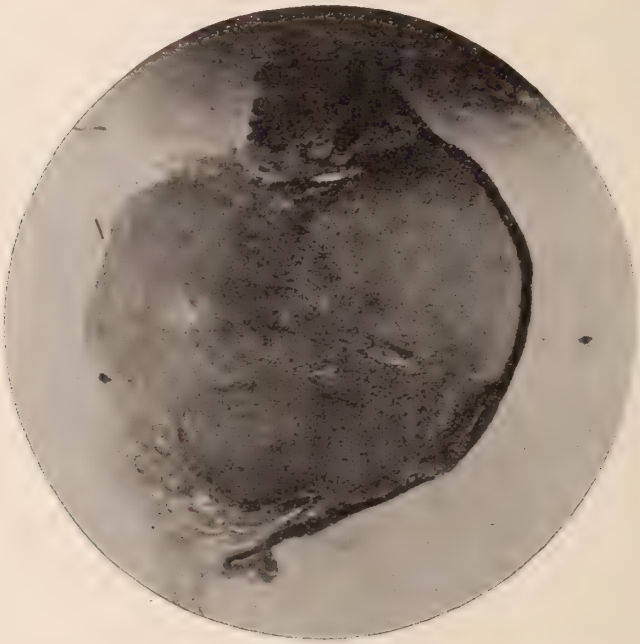

Fig. 1.—Section of caruncle showing trachomatous changes. (Hiwatari)

the above mentioned histologic findings one cannot doubt, that with the case in question we have a genuine trachomatous change of the caruncle. Thereby it is proven for the first time that the trachoma exists also in the caruncle.

Previously I was of the opinion[1] that the formation of the follicles in trachoma are closely connected with the physiologic-morphologic state of the subepithelial layer of the conjunctiva. The case in question appears by superficial consideration not to coincide with this opinion, as the caruncle resembles histologically mostly the structure of the external skin, as it contains sebaceous glands and hair follicles. Many authors, as for instance Waldeyer, Ciaccio, Cirincione, H. Virchow,[2] have, however, already pointed out correctly that the caruncle shows on the other hand the nature of the mucous membranes. One can find here normally mucous cells, disseminated lacrimal glands and diverse migrating cells of varying number. The embryologic examination of Ask[3] and Contino[4] has also proven that in the formation of the caruncle both the skin and conjunctiva are concerned. That trachomatous changes of the caruncle exist, as my case proves, is therefore not at all strange.

The plasmoma formation in the caruncle, mentioned by Pokrowsky,[5] is probably the trachomatous change, as he pointed it out himself as a kind of inflammatory granuloma.

OPHTHALMIC PRACTICE OF TODAY AND ITS BEARING ON UNDERGRADUATE OPHTHALMIC TEACHING

Hiram Woods, M. D., F. A. C. S.

BALTIMORE, MD.

This paper was prepared for the Section on Eye, Ear, Nose and Throat of the Southern Medical Association to be read at its twelfth annual meeting, which was postponed on account of the influenza epidemic. It indicates some of the subjects that must be covered in such teaching, and various points in which ophthalmic practice and teaching diverge from general medicine and surgery, with the errors into which the uninstructed practitioner is liable to fall.

It seems trite to say that ophthalmology should be taught as modern medicine regulates, or should regulate, its practice. But when one analyzes ophthalmology to formulate rules for its teaching, based on modern practice, triteness gives place to a problem of no mean dimensions.

The study of eye anatomy involves nonvascular tissue, its complicated nutrition and drainage. The blood vessels are divided into three distinct groups, practically independent, yet by anastomoses sometimes producing problems in diagnosis.

Eye muscles have peculiar insertions and innervations. All these make up a special anatomy which must be mastered. Ocular physiology introduces optics, vastly important from both the physical and physiologic sides. The muscles must work in harmony with visual adjustment. When ametropia is introduced, harmony is disarranged. Sometimes Nature regulates this perverted physiology; sometimes she fails and we must help. It is not always simple.

Again, there are functional eye defects produced by extraocular influences. Irritation of accommodation may result from causes which in another patient, would produce visible eye lesions. Diabetics frequently suffer from such changes in their refraction. So do the innocent victims of hereditary syphilis. Asthenopia, accompanied by circumcorneal injection, without visible cause, especially in school children, is sometimes the forerunner of uveal disturbance. Refraction error may be absent or variable and glasses do not help. It is often hard to get reliable cycloplegia. Systemic study is as important as if a corneal infiltration were present. There is a medical side of refraction by no means negligible.

Again, consider for a moment the causation of eye diseases. Besides local infection, three causes have long been accepted: syphilis, tuberculosis and rheumatism. Idiopathy has answered the purpose when no one of these has been proven. Beyond gummatous iritis (with a question mark) interstitial keratitis, there is practically no eye lesion solely characteristic of luetic infection. No oculist today should accept a luetic origin in even these diseases or macular choroiditis without other clinical proof or positive Wassermann.

Ocular tuberculosis presents some striking features. It is rarely associated with pulmonary tuberculosis. Keratitis is not infrequent with glandular infection, while the most serious of tuberculous infections, choroiditis, is

often a local process, unassociated with general infection. Diagnosis depends upon tuberculin reaction in the eye: socalled focal reaction. This may be a serious matter. Vaccine diagnosis and treatment can be too glibly handled and one should associate with him in such cases a confrere who understands it.

Finally, "rheumatism" is now hardly a pathologic entity. The form in which it occurs with, or as a cause of, eye trouble is not acute rheumatic arthritis; for it is rare with this affliction; but, in what we still term chronic rheumatism, eye complications are abundant enough. So we must ask what this disease is. So far as I can make out, in modern medical practice, it is considered a result of an infection focus somewhere in the organism. That focus must be hunted down. This is very different from accepting a rheumatic diagnosis because there are muscle pains and we can not explain them. It is equally illogical to rely upon salines, alkalies, salicylates or potassium iodid as remedies when we do not know the underlying cause. However, sometimes we are driven back there because either our search is fruitless or, for one reason or another, the focus can not be removed. As to "idiopathy," the tonsils, sinuses, teeth, intestines, gallbladder, have greatly reduced the number of such cases.

Thus far I have tried to outline briefly some of the essential requirements of ophthalmic practice from two points of view: refraction, which makes up probably three-fourths of our work, and causation of the commoner eye diseases. The oculist's work has alone been considered. Refraction, with its side problems, is his business; so is the etiology of eye lesions. For years we have hammered away at the general practitioner with arguments and urgings to look out for the dangers of ophthalmia neonatorum and to make more use of the eye in general diagnosis. Quite a number have responded and are themselves fair opthalmoscopists. But they soon find they are in the most difficult part of ophthalmoscopy and they have the right to call upon us for help; help not only in seeing changes which might escape them, but in interpreting them. Rigid and unequal pupils, tortuous vessels, increase or diminution in caliber of veins or arteries, retinal edema, exudates, hemorrhages, blurring of neuro-retinal margin, neuritis, old or recent lesion: these are some of the things about which the physician wants to know. Modern ophthalmology puts it up to the oculist to inform him. Mere statements of lesions do not fulfill his needs. Here comes in a most important procedure—perimetry. Thread-like vessels, for instance, may not be abnormal. They are one thing when the field is normal; another when there is concentric contraction for form and colors, especially if contraction advances. Enlargement of the normal scotoma, or scotomata anywhere in the field, are important.

Ocular surgery demands knowledge of, first: the technic of special operations; second, general surgical principles and antisepsis; third, modifications of these demanded by the environment and characteristics of eye tissue. Because of the situation and sensitiveness of the eye, it is impossible to get an aseptic field or to use all the requirements of clean surgery. Recently in my clinic, after a cataract operation, I spoke of the use of iodin tincture in dendritic keratitis. A student asked me why I had not painted the cornea with iodin in the cataract operation. He had seen the skin so sterilized in abdominal surgery and the question was natural. He needed light on special aseptic modifications. It is not my purpose to discuss fully these or other essentials. I am stating only what is commonly known and am doing it for the purpose of definition.

If the practice of ophthalmology requires what I have outlined, how should it be taught? I have been led to write this paper by my experience of three years on the American Board of Ophthalmic Examiners. It has been my fortune to be associated with colleagues who not only realize for themselves the extent of ophthalmology, but want to see education standardized. In the July (1918) number of the *American*

Journal of Ophthalmology, Dr. Edward Jackson, Chairman of the Board, published a most illuminating paper under the title "Defects in Education for Ophthalmic Practice." He concludes, as any one must who knows the state of undergraduate medical teaching, that this work must be largely post-graduate; but the subject of under-graduate teaching is of no less importance.

Let me give one or two examples of the practical results of its defects. In one of my examinations we had a patient with a beautiful simple extraction in one eye and in the other a mature cataract. I asked the candidate to go through the examination of the cataractous eye and tell me whether it would be worth while to operate. He answered (very sensibly as far as he went) that with normal vision in one eye, operation upon the other might not be of much use, but that if dilatation of the pupil showed the cataract was ripe it could be removed. I then asked him to throw out of consideration the operated eye and to determine whether or not there was essential probability of extraction improving vision in the other. His reply was that he could not tell until he removed the ripe cataract. "What g o o d would it do," I asked, "to remove the cataract if the retina or nerve were out of commission?" His reply was, "None, but I can not tell their condition through an opaque lens. I can not see them." That man had been in practice nearly ten years. Had I asked him about light perception, light projection, pupillary reaction, *per se,* he doubtless would have answered correctly; but when it came to applying these physiologic facts to eye surgery, he apparently had never thought of it. In another examination a man who had a good many years of practice told me that he had never had time to take fields because he was too busy with refraction work and ordinary diseases. I asked him how he would make a diagnosis of toxic amblyopia. His naive reply was, "By the history and failure to improve vision with glasses."

Young men are not to be blamed for this. Those of us who hope we have trained ourselves to a higher level of thought, thrashed through the same things until self-dissatisfaction drove us to something better. They and we were taught in our under-graduate life along certain lines. This was followed by the selection of ophthalmology as a specialty. Selection was based upon conceptions which resulted from former teaching. If the latter was faulty, we reasoned on a wrong basis. Early impressions last, and it needs a good deal of determination or hard knocks to throw them off. Maybe, after graduation, dispensary or hospital service was obtained or a brief post-graduate course taken in some clinic, where, as Jackson says, there were ample opportunities for observation of which we could not take full advantage because of our former defective training.

On account of the magnitude of ophthalmology and the impossibility of teaching it adequately in undergraduate life, we have reduced our undergraduate teaching to what we term essentials. In this we have been guilty of two blunders—first, over-specialism; and second, over-simplicity. The former has tended to divorce ophthalmology, at least in the thoughts of the students, from general medicine. The second has failed to train them in the application of pathologic principles to ocular defects. As an example of over-specialism, I want to give an observation of a good many years ago. I visited the clinic of one of our then leading ophthalmic teachers. The chief brought in a patient, a tall spare man in his thirties, who had the stare and gait of the victim of recent nerve atrophy. He had a little vision left. The Professor called attention to the stare, to the dilated pupils and ventured the prophecy that on examination he would find nerve atrophy. So, indeed, he did and reported the fact to the students, none of whom were invited to use the ophthalmoscope. The Chief of the Clinic then whispered something to the Professor and, failing to get a satisfactory reply, repeated what he had said. Then came the reply out

loud: "I don't care if there is a history of syphilis in any stage; the man has nerve atrophy. Bring in the next patient."

The Clinic over, the Chief asked me to stay and go with him to the Dispensary. There was our patient and the Doctor pointed out ataxic gait, lost patellar reflex, etc. Even at that time—in the 1880's—the relation between early nerve atrophy and tabes was well known. All that side of an instructive case, however, was wasted so far as the students were concerned; no cause was given for the atrophy, no outline of investigation suggested by ocular conditions, and the one lesson the youngsters got was the wonderful professional acumen which enabled the lecturer to prophesy nerve atrophy. Only the eye lesion was discussed. If this justly distinguished teacher can be properly criticised for an over-specialized viewpoint thirty odd years ago —as, I think, he can—how much greater the sin of teachers of today who fall into the same erroneous method! Not all cases of nerve atrophy show so clear an explanation as did this. Often from the clinical point of view there is no cause. But what is the duty of the oculist? Blindness is bad enough, but there are conditions which may be added to blindness that can make suffering infinitely worse. The laboratory man, internist and neurologist should take up the study of possibly impending paresis or multiple sclerosis. The oculist should see this started, at least. Treatment, already too long delayed, might avert worse consequences.

Undergraduates should see a close relation between ophthalmology and all departments of medicine. The very presence of optics, with its essential physical, apart from physiologic, problems, has contributed to loose thinking. The optometrist has not been slow to take advantage of this and to spread a propaganda which has, so to speak, taken in a good many practitioners. Having graduated with vague, indefinite ideas of ophthalmology, a physician thinks of the eyes as a cause of headache, for instance. Relying on his own judgment, he wants "the eyes excluded first." He sends the patient to an optometrist, where some seeming refraction error may be corrected, or, at least, made an excuse for selling a pair of lenses. The patient is satisfied that he has done all demanded along that line, the busy doctor forgets or waits for results from glasses before a clinical study. There often result wasted time and unnecessary suffering if nothing worse. Whose fault is it that the doctor going into general practice from the student bench has this false idea of a part of medicine which touches every other part? Whose but the man who taught him? Had proper insistence been laid upon ametropia as one of many possible causes of headache, and emphasis, on differential diagnosis, two results would have followed: the man who afterward became an internist would have become a better diagnostician, and the one who selected a specialty a better doctor. The former would have realized the essential medical nature of the case. Over-specialism did the mischief to both men. Both started with the wrong viewpoint.

I mentioned over-simplicity as another error in undergraduate teaching. Essentially, as Jackson, my lamented friend Wendell Reber and others have insisted, ophthalmology, to be learned thoroly, must be p o s t - g r a d u a t e standardized work; but that does not relieve the undergraduate teachers of responsibility for giving the future specialist proper data on which to base his life work decision, and the future physician a right conception of the relation of the eye to general medicine. With the mixed class and fear of teaching over the heads of most of them, there has come a simplicity of teaching that has made our work little more than presentation of isolated facts. If not linked with pathologic principles, these facts form a wrong basis of thought—unless thinking is put aside entirely—for the man contemplating ophthalmology. They make him look on the specialty as something requiring little medicine. The student who

goes into general medicine forgets them altogether. Neither man will be thus deceived if the ophthalmic teacher realizes that at his clinic and didactic lecture, and in prescribing reading, he has an opportunity of pushing home lessons in general medicine. This might be illustrated from numerous points. Let me take but one—corneal ulceration. Mention has been made of our efforts to prevent the sacrifice of babies' eyes. Integrity of the corneal epithelium is essential if the eyes are to withstand the inroads of infection. Two lessons at once follow: first, the necessity of gentle manipulation in cleaning, together with the danger of an untrained hand introducing a cotton-armed applicator beneath the lids; and secondly, the routine use of cocain to relieve pain following the nitrat of silver drop. If told "why" not only is the fact impressed, but lessons in the function of epithelial tissue are sent home. Or, take the course of an ordinary corneal ulcer from infection to healing. If we make the student understand that injury to sight depends upon density and situation of the nebula or leucoma, we have accomplished something. If we stop there we have done nothing of permanent value. Circumcorneal injection follows the infection. Why? Here are opened pathways for teaching the general behavior of vascular tissue adjoining and nourishing nonvascular structures when something goes wrong with the latter. Atropia usually benefits corneal ulceration, prevents complications and relieves pain. Why? Hyperemia, through anastomosis, congestion and exudates come to our minds. Tell him atropia is used to prevent secondary iritis and he will forget it. Show him why, and he will remember and learn something else besides. A number of years ago I accidentally used the expression "putting a therapeutic ligature on the iridic vessels." If one man has told me that this started him on valuable thinking, a score have.

Cocain as a routine analgesic is positively harmful in corneal ulceration. Go farther; show the function of corneal epithelium in the healing of an ulcer, make clear that the appearance of vessels, shooting their noses from the conjunctiva over the cornea is a harbinger of better things, explain the necessity for these steps toward health and then compare the action of cocain on both epithelium and vessels with what we want, and you have accomplished several things. You have taught ophthalmology and have also linked it with general pathology. You have inseparably connected eye troubles with the basis of all good medical thinking. You can go further, if you choose; you can compare the action of holocain on the vessels and its sparing of the corneal epithelium with cocain. You can show why heat usually helps healing; also, why it may be harmful if the ulcer is associated with purulent ophthalmia; why cold, used for the latter, may do harm to the ulcer. I give this merely as an example of what I mean by linking up general medicine with undergraduate teaching of ophthalmology.

One can think of many other examples. Hypopyon, if presented as a complication of dangerous ulcers, will make no lasting impression; but if explained as an example of the formation of germ-free pus cells in the neighborhood of infection, and that for that very reason it seldom calls for surgical interference, the whole line of thought is changed. It teaches pathology. One could illustrate this by examples taken from lid, uveal, retinal or nerve diseases; but it seems unnecessary to do so.

What I want to make clear is this: the experience of the Examining Board has shown a general lack of appreciation of this method of teaching. There have been conspicuous exceptions. Some teachers are awake to facts; but, many, judging from what we have seen, are following the old course of over-specializing on the one hand and reducing ophthalmic teaching to little more than presentation of facts on the other. It is unfair to students and to the public they will have to serve.

The Board's work of standardizing ophthalmic teaching was necessarily interrupted by the war. When reundertaken, it will, of necessity, chiefly concern postgraduate work. It will en-

deavor to influence undergraduate instruction to the extent of urging teachers to give men a proper basis of thought. Without it, the first task of men entering ophthalmology will be to unlearn a great deal they think they know. So to present ophthalmology to the undergraduate as to impress the man destined for general practice with the truth that this specialty touches general medicine everywhere and that he must include it in his thinking, and to show the future ophthalmologist that in selecting ophthalmology he is not leaving general medicine behind but is merely selecting one branch of practice to which he must apply the principles of general medicine—this is the real problem. How can it be better solved than by founding special teaching on general pathology? If it means more work for the teacher, he must accept it. He should have smear preparations made in his clinic. If he reviews iritis from its clinical side at one clinic, he should give the laboratory findings at the next—Wassermann and tuberculin tests. If an eye muscle is paralyzed the neurologist should take the case for further study and report. But it is useless to pile up illustrations.

Our young men will soon be coming home from across the sea. They have had an environment in which exclusiveness, frills and academic ideas have had to take a back seat. They have had to put up with lack of advantages, right at hand at home, and have accomplished almost wonders. They will bring with them not only new methods and new thoughts, but, if I do not wrongly interpret what some of them have written me, will teach us that a lot of things we hold as almost sacred are unessential, superficial or cumbersome. Their thinking has had to be done on their feet, and it has gone back, with the best of them, to simple pathology. I mean thinking on pathologic principles. One of them wrote me recently that he was profoundly grateful every day for the "fine print in Fuchs." And this fine print is mostly an expression of physiology and pathology in ophthalmic terms.

TRAINING FOR OPHTHALMIC PRACTICE

EDWARD JACKSON, M. D.

DENVER, COLORADO

This paper indicates what the doctor needs to study in preparation for ophthalmic practice and how he may begin his studies. Read before the Pacific Coast Oto-Ophthalmic Society, at Salt Lake City, August 13th, 1918.

It is certain that in the near future systematic training for ophthalmic practice will largely replace the unguided, unadvised, independent working into ophthalmology that has been common in the past. There is no more essential justification of this old plan as a preparation for ophthalmic practice, than there is for the same way of getting into the practice of medicine, which was the common way until a half century ago. There can be no doubt that systematic training, with adequate laboratory facilities and instruction, will give results as much superior to those attained by unsystematic, unsupervised, uninformed, irregular study, in ophthalmology, as it has in the field of general medicine.

But this is a formative period for training in ophthalmology. To shape a curriculum wisely, we need the best light that can be thrown on the subject from our individual experiences; not only the conclusions of teachers, but also the impressions of those who look back only upon their own individual difficulties and mistakes. The fact that our methods and means for study have varied so widely—have been so individual—can be helpful in planning for better ways of reaching

a more perfect result. It would be something worth while for every ophthalmologist to state briefly what has been most helpful to him in his preparation for ophthalmic practice, and what he has found to be the obstacles most difficult to overcome. All who may read this paper should write out and publish their important educational experiences.

To begin with some of my own: I was one of the very few students in the class of 1878 at the University of Pennsylvania who regularly attended the clinical lectures of Professor Norris and the special courses of Drs. S. D. Risley and E. O. Shakespeare on ophthalmology, or who got an ophthalmoscope when he graduated. But I had been in practice a year, and older colleagues were referring eye cases to me, before I ever read or heard the word glaucoma. Clinical courses are essentially not systematic, and Drs. Risley and Shakespeare only undertook to teach certain special departments of ophthalmology.

The undergraduate student of today is better taught. But until graduate teaching is also made systematic there will be such glaring deficiencies in our training for ophthalmic practice. We must have a curriculum that will cover the whole subject, so that even the man who has not covered it completely may have a chance to know wherein he is deficient.

Systematic training must begin with the fundamental branches. This is not furnished to a sufficient extent in any medical undergraduate course. In the study of the special anatomy of the eye, or physiologic optics, the need of the general medical student here dominates. When one plans to take up the special line of ophthalmic practice, he should study these subjects over again; and with much more minuteness and thoroness. Much of the anatomy is to be studied with the microscope; and with the ophthalmoscope, which is in effect a low power microscope.

Physiologic optics should be studied largely by experiments. There should be laboratory courses, best taken with adequate apparatus and under supervision. The practitioner who is shifting from general to special practice may be able to fix up the needed apparatus at no great expense, but he will miss the supervision. It would be a real gain if young men could be induced to take these courses before getting tied down in special practice. It is certainly as well worth while to leave home for them as for the clinical courses that are so generally taken.

As to ocular anatomy we have all of us started on right lines, only we have not gone far enough. The plan of study pursued in the undergraduate course on anatomy is good; but to furnish a sufficient basis for ophthalmic surgery it must be carried to minute detail. We must deal with millimeters, not with inches. We must know how far back from the corneal margin is the attachment of the internus, how wide it is; how deep is the anterior chamber, how much of its angle is concealed by the overlapping sclera. Minute topographic anatomy is important; and dissecting, here running into microscopy, is essential.

Three lines of work must be followed: Study of the dead human eye, carried over into study of all adjoining and related parts; study of the histology of the eye, carried on by means of the eyes of lower animals obtained immediately after death, and supplemented by the study of enucleated human eyes, and those of stillborn children; and study of the living human eye with the magnifier or corneal microscope, and the ophthalmoscope. This is the branch of fundamental study fitting for ophthalmic practice that the student is usually best prepared to carry on alone, or with such help as careful reading can afford.

My own preparation to take up work on the refraction and accommodation of the eye was rather fortunate. I had studied engineering before studying medicine; and with college physics had a good deal of mathematic optics. But such preparation is accidental and exceptional. The lack of it has been felt by many ophthalmologists and strikingly manifested by some who did not feel it. In the Transactions of the

American Ophthalmological Society a former member expressed the view that an oblique position of the retina could cause regular astigmatism. Two other members indulged in a controversy as to who should have credit for priority in using two cylinders with axes crossing at an oblique angle; both in complete ignorance of the fact, that the optical effect of such a combination could be better obtained by use of one cylinder, of appropriate strength and direction, with the proper spherical lens.

When the late John Green, a graduate of Harvard, was nearly 60 years old, had been a member for twenty-five years of the American Opthalmogical Society and was a recognized authority in ophthalmology, he became so conscious of the deficiencies of his training in mathematic optics that he went to a colleague in the Faculty of Washington University, and got him to lay out for him a course in mathematics. Dr. Green studied this course, and afterwards published some of the most advanced and valuable papers on mathematic optics that have appeared in this country. That plane trigonometry is not required as a preliminary to the medical course, does not do away with the necessity for a knowledge of it, to understand clearly the first laws of refraction, or lessen the handicap that ignorance of it always proves in studying physiologic optics.

As to the pathologic anatomy and histology of the eye, the great mass of ophthalmologists fall into one of two classes; those who know they are deficient in this branch, and those who have never thought deeply or studied their cases thoroly enough to find this out. Of course, there are many sub-classes, as: Those who keep struggling along and trying to learn what they can; those who conclude they are too old or too busy to study a new branch; those who believe that an examination of their specimens by a general pathologist is all that is necessary, missing the great ocular significance of the different varieties of cells composing infiltrates, and taking some one's ipse dixit that the case is one of sarcoma, when the diagnosis may be as obscure or as doubtful as one regarding the etiology of iritis; and the class that doesn't believe pathology would help them prescribe glasses, or extract a cataract or collect more money, or do any of the other things that their hearts are chiefly set upon.

I graduated in the last class that went out from the University of Pennsylvania without having to spend a day in a histologic or pathologic laboratory. The shadow of coming events in the new curriculum set me to working with a microscope during the days of waiting for practice. The first sarcoma I studied came from the orbit of a cow, the first fresh eyes from cats and a puppy. Yet, urged on by a sense of lacking something that I should have had, and working with fair enthusiasm, I still feel that I have missed much of the educational value of my cases; because I never had any *systematic* training in ocular pathology, or the guidance and suggestion of one who had been over the ground before me, or had made himself a master in this branch. I still hope to know more than I yet do of this subject, but the years in which such knowledge would have been of the highest value are gone. Let us give those that come after us a better chance.

It is not meant that we should all, or most of us, become expert technicians, or dispense with the aid of the men and women who make pathology their specialty. But each of us should be able to sit down with a good well-stained section, and see what is there, and appreciate its significance. We will never be masters of ophthalmology until we can do it.

The young men trained in the last few years in general pathology, as it is now taught in the best medical schools, have a broad foundation on which individual study can erect a good working knowledge of ocular pathology. But they probably more than anyone else, will appreciate the value and importance of a systematic course under skilled guidance.

Of the study of clinical and operative ophthalmology, little need be said.

No one who has had thoro training in the fundamentals of ocular anatomy, pathology and physiologic optics is likely to neglect them. Students untrained in the fundamentals leave home and eagerly crowd into large clinics for six weeks' courses; from which they can get but half the benefit that they would derive therefrom after better preparation. They pay willingly for the chance to learn the technic of operations, they are not yet prepared to advise, with benefit either to their patients, or to their own professional reputations. When they come to clinical opportunities properly trained to understand and appreciate them, there can be little doubt that they will fully profit by them.

In view of his real needs, and of the actual opportunities for instruction that are offered in America at the present time, what can we advise the student who desires to fit himself for ophthalmic practice? Assuming that he has had a good postgraduate year of hospital work in general medicine or surgery, my answer would be something like this: Begin by going thoroly over the teaching regarding the eye and its related parts as given in the larger books on anatomy, including dissection on the cadaver if possible; and with reference of each structure to the principal landmarks of the skull and of the living head. Supplement this by careful dissections of the eyes of the puppy and kitten, and histologic studies of such eyes, made on material properly fixed, cut and stained.

In addition get into the habit of making careful observations of the anatomic variations in the eye and its adnexa in different patients, as the colors and structure of the iris, size of lids and palpebral opening, prominence of eyeball, abundance and characters of the lashes, position of the lacrimal puncta, distribution of the conjunctival vessels, and the orifices and bodies of the Meibomian glands. Learn to draw all the structures and appearances studied as a means of cultivating the power of exact observation; and compare such drawings with the figures found in the different books.

Finally study with the ophthalmoscope the anatomy of the normal eye ground, comparing what is seen with the account of this anatomy given in Loring's Textbook, Volume I, Lindsay Johnson's Atlas, or Adam's Ophthalmoscopic Diagnosis. Compare the different representations of variations in the normal fundus with the discussion of their anatomic basis and significance.

Such a systematic course in the anatomy of the eye is suggested to be carried on by the student himself, with such help as may be obtained by consultation with any well-trained ophthalmologist. It is not in any institution. But parts of it and opportunities for laboratory work are given in many institutions; and any of these will be helpful if the student does not overlook the points in which they fail to come up to the complete course.

Next after the course in anatomy, and over-lapping it if time is available, may come the work in physiologic optics. The trigonometry needed and the physical and geometric optics may well precede the anatomic studies. Trigonometry can be studied with any teacher of high school or college mathematics. Even if it has been studied before, a review of it will save more than the time required when it comes to the study of foci, nodal points, size of images, etc.

Physical optics should be studied with experiments. If a properly equipped physical laboratory is available, the best work can be done in it. But for the larger number who cannot enjoy its aids, much may be done with simple apparatus. A convex and a concave lens, a prism, a cylindric lens, a source of light that approximates a point, a screen of cardboard to receive the image and a graduated scale to measure distances are the essentials. These should be always at hand to reproduce the proposition stated in the book, to actually visualize and render clear what would otherwise receive only a perfunctory assent and an uncertain place in the memory.

With the needed apparatus read Hartridge, Chapters I to V, or the

corresponding chapters in the larger textbooks, as in de Schweinitz, Chapter I; Weeks, Chapter III; or Fuchs, Part III, as translated by Duane. The writer is disposed to recommend his own chapter in Volume I of the System of Norris and Oliver, because it gives the important facts of refraction, without recourse to algebraic formulas, which always present great difficulties to the student who is not habitually working with them. There are many other excellent accounts of this subject. The essential thing is to read one of them carefully, and to test every statement possible by an appropriate experiment.

After physical optics has become familiar, the actual clinical work of measuring ametropia may begin. Here more than anywhere else the thoro working out of single cases is of the highest educational value. It is better for the young refractionist to take a week of his office hours to work out one case thoroly than to give an approximate correction in twenty cases from the same number of hours of study. With practice, speed in such work will gradually be acquired; but unless the habit of thoroness is thus established this first essential for success in the prescribing of glasses will never be attained.

Whatever views may be held as to the need of cycloplegia in the measurement of refraction it is certain that the beginner should study many cases, both during and after cycloplegia. If he has done this he can form his own judgment with regard to cycloplegics. If he works only without cycloplegia he will never get the exact understanding of this branch of ophthalmology that everyone who engages in ophthalmic practice ought to have. In regard to disorders of ocular movements also: The same thoroness of early studies, both the fundamental and physiologic aspects of these movements, and the minute investigation of individual cases are required.

The greater part of clinical ophthalmology is diagnosis. It is diagnosis that requires time and thought. It is diagnosis that furnishes the foundation for therapeutic success; and in every department it demands thoroness. The ophthalmoscopist must use both the direct and inverted image. If he neglects the former he will never see the fine fundus changes that are so important in general medicine. If he ignores the latter he will fail to see the fundus in some cases in which it is his duty to recognize changes that exist there. If he knows but one way of measuring the muscle balance, or taking the field of vision, he is not well trained for ophthalmic practice.

With regard to the therapeutics of ocular conditions. Breadth of view and exactness of application are needed. But failure in this direction is far more frequently due to lack of training in the theory and diagnosis of ocular diseases, than to neglect of actual applications of curative drugs and operations. Skill in treatment grows gradually with experience thru years of practice. The best the beginner can do toward attaining it is to lay solid foundations of anatomy, physiology, pathology, physics and chemistry on which a wise application of therapeutic agencies must always depend.

To summarize: The beginner in ophthalmic practice should realize that he is a beginner. Specialization in his work can only be justified by special knowledge which as a student of general medicine, or a general practitioner he did not possess.

This special knowledge should be gained in a certain natural order; beginning with elementary studies of which he is generally quite as ignorant as he is of desired refinements of diagnosis and therapeutic skill. These elementary studies should be taken seriously; attacked first and pursued with all the thoroness of which he is capable.

After they are mastered he is ready to begin with profit, where it has been too common to start in the past, to make a broad clinical acquaintance with ocular defects and diseases.

CAUSES OF HETEROCHROMIA IRIDIS WITH SPECIAL REFERENCE TO PARALYSIS OF THE CERVICAL SYMPATHETIC.

F. Phinizy Calhoun, M. D.

ATLANTA, GA.

This abstract of a candidate's thesis presented for membership in the American Ophthalmological Society, includes the reports of cases, a general review of the literature of the subject, the results of experiments, and histologic observations on the effect of extirpation of the cervical sympathetic in the rabbit, the conclusions reached from the investigation, and a bibliography.

That curious condition which consists in a difference in the pigmentation of the two eyes, is regarded by the casual observer as a play or caprice of nature. This phenomenon has for centuries been noted, and was called *heteroglaucus* by Aristotle[1]. One who seriously studies the subject, is at once impressed with the complexity of the situation, and soon learns that nature plays a comparatively small part in its causation. It is however only within a comparatively recent time that the pathologic aspect has been considered, and in this discussion I especially wish to draw attention to that part played by the cervical sympathetic.

Many writers have given Hutchinson[2] (1869) credit for first describing a difference in the color of the irides, with which cataract was associated. I by chance discovered that Lawrence[3] (1853) described irregularities in the color of the iris and cited two cases; in one of slowly changing color, and another of changed color of the iris with cataract. He also quoted Wilde[4] who mentioned the fact that heredity plays an important part in many of these abnormalities.

NOMENCLATURE

Various terms have been applied for this inequality in the color of the irides, such as *heteroglaucus* of the ancients; Weill[5] uses the word *heterophthalmus; anisoiridochromia* is mentioned by Scalinci[6] and *chromoheteropia* is suggested by Malgat[7], who also thinks that the word heterochromia should apply to those cases in which parts of the same iris have different colors. In those cases where a cyclitis accompanies the iris decoloration, Butler[8] uses the term "heterochromic cyclitis," but the "Chronic Cyclitis with Decoloration of the Iris" as described by Fuchs[9] undoubtedly gives a more accurate description of the disease, notwithstanding its long title. The commonly accepted and most universally used term *Heterochromia Iridis* exactly expresses and implies the picture from its derivation (*ξτεροσ other, χρωμα*) color. Other newly coined words only add disorder to an already chaotic classification of diseases.

Dr. Willis H. Bocock, my friend and former professor of Greek at the University of Georgia, has suggested the word irideterochromia. "The *o* (as in iridoplegia) is not used in composition before a vowel; therefore *irid* in the word above. *Hetero* (as in heterochromia) loses the *h* in composition, therefore *irideterochromia.*"

While it would be advantageous to have the meaning so expressed in one word, its derivation would not be as obvious as the term heterochromia iridis, unless the reader possessed a working knowledge of Greek.

CLASSIFICATION

Any exact classification of this condition is almost an impossible task, and mindful of its limitations I venture to

submit the following as a working basis of study:

Primary..	Congenital	With or without	Heredity.	
			Sympathetic paralysis.	
			Cyclitis and cataract.	
	Acquired..	With or without	Sympathetic paralysis.	
			Cyclitis or cataract.	
Secondary.	.....		Injuries. Siderosis bulbi.	
			Uveal infection—Myopia.	
			Glaucoma.	

Strictly speaking, as Sym[10] has pointed out, there could be no such thing as a congenital form of heterochromia iridis, since it is about the twelfth or sixteenth month that the child's iris ceases to be light and takes on color. Brown pigment has however been noted to appear on the iris as early as six months.

I am not in accord with Sym and Scalinci who maintained that we should reserve the term heterochromia iridis for the instances in which there has not been any obvious pathologic process in the eye, such as glaucoma or iridocyclitis. The term expresses the condition regardless of the cause. I have recently seen a case in which there was a decoloration of the iris in an adult negro, who at first glance presented evidences of a sympathetic paralysis, namely a smaller pupil and a narrower palpebral aperture than[10] the opposite eye. The case proved to be the result of an injury received during childhood, and the presence of a foreign body in the choroid could be demonstrated. The ptosis was traumatic, the myosis was due to posterior adhesions, and the iris decoloration was probably a siderosis bulbi, or caused from a low grade iridocyclitis. I can see no objection to classifying this as one of heterochromia of the iris, of secondary origin due to an old injury (foreign body with uveitis).

HEREDITY

Heredity as a cause for heterochromia iridis, has not received the same consideration from modern writers as from those of a generation ago. I am firmly convinced that there are many such congenital cases without sign of development of a pathologic lesion. And one reason why more cases are not so classified is that the observer, indifferent to the causes of heredity, does not stress its influence, and also that too few of our patients (clinical patients especially) know enough of their ancestry.

The history of cases I and II from the same family (more fully described under the heading of symphthetic paralysis) where the paralysis and lighter iris were all on the same side, in a manner substantiates the fact that heredity does play an important part. If the paralysis was the cause for the iris decoloration it would be proper to consider it as *the disorder* inherited.

Galezowski[11], Bistis[12] and Scalinci[6] report cases of sympathetic paralysis, where one or more children in a family had iris decolorations which were inherited. But we should bear in mind Priestley Smith's[13] words that "heredity is not in any real sense a cause. It may account for the presence of a disorder in an individual or family, but it tells us nothing as to its origin. In some former generation there must have been a first departure from the normal."

Osborne[14] as early as 1849, drew attention to the difference in color of the irides of a person (that is they were irregularly marked), who had fifteen brothers and five sisters who all possessed the same abnormality which was derived from the mother, whose three sisters and one brother had the same which were again derived from the mother's side. Gunn[15] mentions similar cases and classifies them as "piebald iris."

It has been stated many times that in congenital heterochromia iridis the color of one eye is inherited from the father, while the color of the other is derived from the mother. In many instances this has been true, but the reverse is as often the case, and even eyes of an entirely different color to either parent have been observed. This contradictory observation however would not refute the hereditary theory of transmission, bearing in mind the principles of Mendel's Law.

The family reported by Gossage[16] is the only recorded case beyond the second generation that I find mentioned. A detailed description and examination of the eye unfortunately is not given, altho the author states that "in this family heterochromia of the iris tended to appear when one eye, always the left, was grayish blue in color, with chestnut brown patches. Of the offsprings of the affected members of the family eight were affected and twenty-two free."

From a genetic point of view, Przibram's[17] work on angora cats is interesting. He found that the union of an

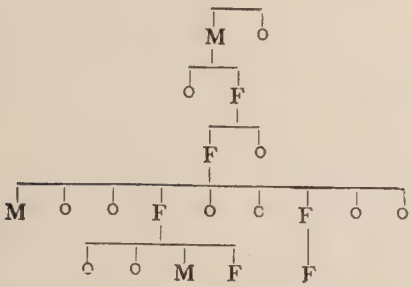

Fig. 1. Gossage's case. M, affected male; F, affected female; O, sex undetermined.

asymmetrically colored animal having one blue and one yellow eye, with a symmetrically colored animal having two blue or two yellow eyes, resulted in the production of both asymmetrically (heterochromia iridis) and symmetrically pigmented offsprings. He concluded that asymmetric animals can be traced back to asymmetric ancestry and that either color of an asymmetric parent can appear in the symmetric form of an offspring.

PARALYSIS OF THE CERVICAL SYMPATHETIC

Within the past few years attention has been directed to the association in heterochromic eyes of alteration of a paretic nature of the cervical sympathetic. In fact some observers, notably Bistis, are so enthusiastic over the close association that they have added to the classical Horner's Syndrome (ptosis, myosis, anhidrosis, hemiatrophy facialis) heterochromia iridis as a symptom. Mayou[18] in 1910 was probably the first to accurately describe these changes, although Horner (quoted by Samelsohn[20]) as early as 1875 did draw attention to a case in which a light iris occurred on the same side with a ptosis of sympathetic origin. In all only thirty-three cases have been reported, ten of which were complicated either with cataract or a slow uveitis.

The following authors reported: Galezowski[11], 2 cases, 1 complicated; Horner's case reported by Samelsohn[20]; Dethleffsen[21], 5 cases, 1 complicated; Lutz[22], 13 cases, 3 complicated; Hutchinson[2], 1 case; Alexander and Lander[32], 5 cases, 2 complicated; Bistis[39], 2 complicated cases; Mayou[18], 3 cases and Scalinci[6], 1 case.

From my own observation I can report four cases; the first two being of the same family with positive symtoms of a sympathetic paralysis. Case III gave less prominent symptoms, and case IV presented only slight evidences of any sympathetic disturbance. My reason for here reporting case V along with the others, is that we may assume that the heterochromia was due to certain trophic disturbances from a complete hemiplegia.

Properly it belongs under the acquired classification, if the history is correct.

Case I. Baby R., male, age ten months, seen September 30, 1908; parents first noticed a drooping of the upper lid and a lighter color of the right eye when only a few weeks old. The father and mother are blonde and have blue eyes. The mother of the patient has a paternal aunt whose right eye is of lighter color; her brother has a drooping right upper lid with a lighter colored iris on the same side. This brother has a son (case II) with the same abnormality on the right side. There is also another brother whose eyes are of the same color, and whose son has a drooping upper lid and light eye on the right side. This patient (baby R) was born normally and has been healthy. The parents have noticed that the child

did not perspire on the right side of his brow.

The examination showed on the right side a decided ptosis, small pupil, light blue iris, and a dryness of the skin. As well as I could detect without a dilated pupil (the parents refusing eye drops) the fundus was normal and there were no corneal deposits. In July, 1915, nearly seven years later I again examined the child. He had been well and healthy. The upper right lid still drooped, but not greatly, there was some suggestion of a facial atrophy on the same side, the pupil was still quite small compared to the left eye, yet it reacted well to light; the iris was blue, vision 20/20 and fundus was normal

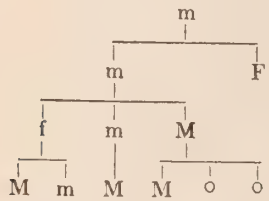

Fig. 2. Author's case. M, affected male; F, affected female; m, normal male; f, normal female; o, sex undetermined.

with no corneal deposits (without mydriasis). The left eye was normal and the iris brown. (Fig. 2.)

Case II. Master D, age 5. The family history is the same as case I, the patient being his first cousin. The maternal grandmother gave me the history of the family and patient, and she stated that the condition to be described existed from birth. The patient's father (uncle to case I) has blue eyes and the mother's eyes are hazel and I am told she is blind in one eye "from the rupture of a blood vessel." At birth there was some abnormality (a breech presentation) although no instruments were used. There are two younger children with normal eyes of the same color.

Examination: Right, drooping upper lid, facial hemiatrophy, palpebral fissure measured 5 mm., pupil active to light, 2 mm. in diameter. Color of iris was blue. Two drops of 1-1000 solution epinephrin did not dilate pupil. Cocain not used. Fundus normal, no corneal deposits. Vision 20/20. Left, dark blue iris, with brownish pigmentation surrounding pupil, which measures 4 to 5 mm. Fundus normal. Vision 20/20.

The grandmother states when the child is unwell, the drooping of the upper lid and the narrowing of the pupil of the right eye are perceptibly increased. Perspires on left side of face only. (Fig. 2.)

Case III. J. L. M., male, age 57. States that all of his life the left eye has been smaller than the right and of a lighter color. Family history negative, all children have dark eyes. The patient was brought to me as a refractive case on account of headaches and dizziness. Patient is a brunette. Two years ago he had a stroke of apoplexy causing left hemiplegia, which now partially exists. He gives a positive luetic history, and has taken appropriate treatment including salvarsan.

Examination: Right 20/15 corrected. Palpebral aperture 12 mm. Iris brown; pupils active to light and measure 2.5 mm. Fundus shows many small vitreous opacities, but no corneal deposits. Typical retinal arteriosclerosis, i. e., beaded and corkscrew arteries. Pupil does not dilate to epinephrin, and sluggishly to cocain, as compared to left. Tonometer 20 mm. Left 20/20 corrected. Palpebral aperture 10 mm. Iris light grey and active to light. Pupil measures 3 mm., does not dilate to epinephrin, but actively and widely to cocain. Fundus no corneal deposits, but similar vitreous opacities and retinal changes as in right. Decided left facial hemiatrophy and apparent enophthalmos. No anhidrosis. Tonometer 20 mm., Hg. Visual fields contracted peripherally. Systolic blood pressure 172 mm. Hg.

Case IV. J. E. M., male, age 38. Family and hereditary history negative. Father's eyes brown, mother's blue. Patient is only member in family with differently colored irides and he states that he has had this difference all of his life. He consulted me for pain in eyes after reading.

Examination. Right eye comp. H.

astig. Vision 20/20. Pupil same size as left and reacted to light. Color of iris gray. Slight drooping of upper lid. Palpebral aperture 6 mm. Fundus normal. No corneal deposits.

Left eye. H. astig. Vision 20/20, pupil active to light. Color of iris brown. Palpebral aperture 8 mm. Decided bluish discoloration of sclera arranged in patches above and out, and down and out. After using the same number of drops of homatropin in each eye for an hour to dilate the pupils for retinoscopy, it was observed that the right (light iris) was dilated to maximum with loss of accommodation, whereas the left pupil still reacted to light, with little loss of accommodation. Prolonged use of the drops did produce cycloplegia. Seen one month later. Slight ptosis on the right side and right pupil 2.5 mm. whereas left 2 mm. No response to epinephrin and right pupil dilated to 4 mm. after twenty minutes use of one drop of cocain. Left did not dilate. The only additional evidence of a sympathetic paralysis was a slight ptosis on the lighter side.

Case V. P. R. R., male, age 43, consulted me on account of defective sight of long duration in the right eye. Several members of his family have bad eyes, evidently refractive errors and perhaps from ocular injuries. Blue or gray colored eyes predominate in the family. The patient is a decided brunette with black hair and states that when several months of age he was paralyzed on the entire left side of body and face. He states that the left eye has always been of lighter color than the right. The patient is a farmer of moderate intellect. A general physical and neurologic examination was made by Dr. H. Crenshaw, who reported nothing abnormal except a general left hemiplegia and there were no positive evidences of a sympathetic paralysis. The eye examination is as follows: Right, vision, light perception, extraocular muscles normal, pupil dilated and inactive, measures 5 mm. Iris light brown, with one area of intense brown pigment above and a sector shaped area of gray below. Media clear. Typical cupping with atrophic changes of glaucoma simplex. Tension 52 mm. Hg. Corneal anesthesia. Left, vision 20/30. Small pterygium. Pupil 2.5 mm., wide, active, iris gray, slightly shallow A. C., no drooping of upper lid. Fundus normal, cornea sensitive, no deposits. Field contracted peripherally with an encroachment on nasal side. No enlargement of blind spot nor scotoma. There was no anhidrosis; but there existed a decided asymmetry to the face; the left side much sunken, with a deepening of facial furrows. We assumed that the facial atrophy was due to the general hemiplegia and not to a seventh nerve involvement. It is difficult at this late day to explain in this case any direct connection between the light iris and facial hemiatrophy or hemiplegia on the left side, unless we can imagine that in infancy certain trophic disturbances developed as a result of the hemiplegia, but even this gives nothing very definite.

In closely reviewing the thirty-three cases reported it is very noticeable that in a good percentage the only evidence of a sympathetic alteration was a narrowing of the pupil in the lighter eye. While this is evidence of a sympathetic paralysis, it is not altogether positive. In case III which I believe to be of sympathetic paralysis (having ptosis and facial hemiatrophy), the pupil was larger and dilated under cocain more readily than its fellow. I take for granted that the authors have eliminated the many other influences which would cause a small pupil, before positively declaring the case as one of sympathetic disturbance. In this connection it is interesting to note Pollock's[23] well known experiment in which he caused a dilation of the pupil from a mydriatic and a contraction by direct light in cases where he had completely excised the superior cervical sympathetic and the ciliary ganglia.

Pollock concluded after his experiments that "evidence is given that a motor plexus with nerve cells exist in the sphincter and in the dilatator pupillae of the rabbit's iris. This plexus lies between the individual cells of the muscles and contains fibers of extreme

tenuity. The plexus persists after separation of the iris from the central nervous system. It may, therefore, be regarded in the same nature as the plexus of Auerbach and Meissner in the intestines."

It should also be borne in mind that in rabbit experiments where the superior cervical sympathetic ganglion has been completely removed there is often a paradoxic dilation of the pupil. The phenomenon has been observed by Langendorff[24], where several days after the ganglion has been removed the pupil markedly dilates, and he explains it by vasomotor changes, i. e., dilatation of the iris vessels causes the pupil to contract, while a narrowing produces a dilatation of the pupil. This vasomotor change also takes place in the ear; at first an increased warmth, and then later a coldness.

Another fact to be noted from the reported cases of heterochromia iridis associated with undoubted sympathetic paralysis is that the paralysis was usually congenital or first noticed in early infancy; and the difference in the color of the irides developed at the natural time when changes take place in the color of the iris. In several cases (Mayou[19]) there was a history of forceps delivery, which was naturally supposed to be the cause of the paralysis.

However it is not difficult to find equally as many reports of a sympathetic paralysis from forceps delivery without iris decoloration (Reese[25] and Burrows[26]) altho in many of these reports no reference is made to the color of the iris. This lack of depigmentation in light colored irides of blondes with an associated sympathetic paralysis can easily be explained. Mayou[27] has also mentioned cases of sympathetic paralysis without iris decoloration associated with cervical rib. Of all the reported cases of sympathetic paralysis developing in adult life Bistis[28] reports the only positive case where a change in the color of the iris subsequently developed; and the case is well worth reviewing.

Bistis' case. Female age 38. The mother showed differences in the color of the irides and the lighter eye showed cataract in an advanced age. For two years the patient's sight had failed and the color of the right iris has changed. There was pain around the right eye, facial hemiatrophy with anhidrosis of same side that appeared at same time as heterochromia. Author had seen patient much before onset of trouble and the condition described did not then exist. The eye showed ptosis, enophthalmus, descemetitis, blue iris, pupil does not dilate as well to cocain as opposite side, no effect by epinephrin. Aqueous slightly turbid, tension subnormal and lens changes.

Metzner[29] reports Mendel's case in which there were certain suggestive peripheral depigmented changes in the iris.

A traumatic paralysis of the superior cervical ganglion or nerve in adult life is by no means an uncommon accident, and as yet no reports have been made of a subsequent iris decoloration. I personally have followed two such cases. I have also inquired of the older ophthalmic surgeons of large experience, who at one time advocated and practiced sympathectomy for glaucoma, and in no instance has there been noted any subsequent change in the color of the iris.

SUGGESTED ALLIED CAUSES.

It is noted that in case III there existed slight deafness, which from the history and examination suggests nerve impairment. I can offer no opinion from this limited experience as to whether there is any association between the auditory, ocular and sympathetic disturbances. Mendel[30] mentioned a similar change in one of his cases. It is well known that deafness is often present in albino cats (Beaumont[31]) and in two cats which had heterochromia iridum and deafness, Alexander and Lander[32] studied the anatomy of the eyes and ears. They found an absence of pigment in the perilymphatic cells of the auditory organ, and on the other hand the mesodermal pigment was absent in the lighter iris.

These same authors called attention to the influence which certain gland like

structures at the posterier part of the ciliary body first described by Collins[33], might have in producing a depigmentation of the iris. According to Griffin[34] these glands control the amount of pigment in the eye, as shown by their absence in albino eyes and their imperfect development in feebly pigmented blue eyes. As plausible as this theory seems, the presence of these glands are nevertheless doubted by other able men, Alt[35] and Rutteman[36], who were not even able to find their lumen. Finnoff[37] finds these so called pigmented glands, but thinks that they are pigmented plugs; and while he admits that gland like bodies may be demonstrated, he considers the lumen an artefact produced by the process of hardening; and a section of such tissue would resemble a tubular-like gland cut cross-wise. Therefore with this apparent uncertainty, we could hardly accept at the present time the suggestion that the so called ciliary glands of Collins have any influence in causing heterochromia iridis.

EXPERIMENTAL WORK

In regard to the experimental work, which has been done on animals by dividing the sympathetic nerve, or excising the superior cervical ganglion, Angelucci[38] found that section of the ganglion produced trophic alterations of the eye; among them being a disappearance of the pigment of the iris, with an atrophy and depigmentation of the choroid, besides certain well defined alterations of the blood vessels of the iris. Bistis[39] produced similar changes in the iris, and in one case he was able to demonstrate a cloudiness of the aqueous, and find in sections deposits on the posterior surface of the cornea, which to his mind was highly suggestive of an inflammatory process. Later Metzner and Wolfflin[29] added evidence that a sympathetic paralysis caused a distinct loss of pigment in the iris, and also recorded other changes which had previously been observed, such as epiphora, flattening of the cornea (Angelucci), changes in the motility of the nictitating membrane and hypotonia. This latter observation was to a certain extent agreed with in our experiments.

By more recent experiments on rabbits these same authors concluded that the superior sympathetic ganglion must have an independent tonus as regards the dilatation of the pupil, for if on one side division of the nerve was made below the ganglion, and on the opposite side the ganglion was extirpated, the pupil was smaller on the extirpated side. Their experiments also showed that the extirpation of the ganglion was never accompanied by a depigmentation of the iris, but that a resection of the nerve below the ganglion was followed by a decoloration of the iris. These last mentioned experiments present new phases to the subject with which we have had no experience, and which are quite contrary to the generally accepted physiology of the sympathetic system.

In this connection it is of interest to know that Galezowski reported a case of heterochomia where in the lighter eye, the pupil and the palpebral fissure were wider and the eye was more prominent than its fellow. Obviously there were symptoms of a sympathetic stimulation or irritation.

THE AUTHOR'S EXPERIMENTS

An excision of the cervical sympathetic ganglion was made in the rabbit.

Guinea pigs were first employed in our experiments, mainly to perfect the operative technic of the removal of the superior cervical ganglion, and later Belgian hares were used. After the operation the ganglion was preserved in normal saline solution, later stained with methylene blue (vital stain) and examined microscopically.

Light ether anesthesia was administered, the fur on the under surface of the neck was shaved, the part washed with soap and water, sponged with alcohol and then painted with tincture of iodine. The ganglion was rapidly exposed and grasped with a pair of tissue forceps and excised with scissors. The skin incision was closed with continuous silk sutures and a sterile

gauze dressing applied with adhesive tape. Apparently the animals did not suffer in any way from the operation and were quite alert shortly afterwards. There were no infections.

As the rabbit's pupil is often oval (the vertical diameter being the greatest) pupillary measurements were made with a millimeter rule along the horizontal meridian of the cornea, that is from canthus to canthus. The eyes were exposed to daylight from a northerly direction. Tonometric readings were made with the Schiotz instrument and it was applied the moment after an instillation of one drop of a 4 per cent aqueous solution of cocain. The lids were gently retracted with the fingers, and usually the readings were easily and presumably accurately made; although at times the animals were exceedingly nervous and frightened which apparently accounted for the wide variations in the intraocular tension.

The 7.5 milligram weight was employed, but when there was doubt of the accuracy, other weights were used as controls and the readings usually corresponded.

It was exceedingly difficult to distinguish early decoloration of the irides, and it is possible that one's imagination had its influence in causing certain discrepancies made in our early observations, but when a decided change was noted, this opinion was concurred in by three or four other observers. Eyes which showed no great change in the color during life presented a marked difference after enucleations and when held side by side for a closer comparison.

Five guinea pigs were used, and the four that survived, all showed a narrowing of the palpebral aperture and myosis, but no microscopic change in the color of the iris on the operative side even seven months after the operation. Weeping of the eye on the operative side was noticed as a symptom in three cases after recovery from ether anesthesia and later disappeared. The detailed account of these experiments is published in the Transactions of the American Ophthalmological Society v. 16, p. 291-298.

TABLE 1.

Tonometric readings of the right eye before and after operation:

Rabbit No. 1—Average tension before operation, 22 mm. hg.; total average after, 24 mm. hg.

Rabbit No. 3—Average tension before operation, 27 mm. hg.; total average after, 22 mm. hg.

Rabbit No. 4—Average tension before operation, 26 mm. hg.; total average after, 21 mm. hg.

Rabbit No. 5—Average tension before operation, 25 mm. hg.; total average after, 14.8 mm. hg.

Rabbit No. 6—Average tension before operation, 27.3 mm. hg.; total average after, 22 mm. hg.

Rabbit No. 7—Average tension before operation, 21 mm. hg.; total average after, 12.1 mm. hg.

Rabbit No. 8—Average tension before operation, 7 mm. hg.; total average after, 17.8 mm. hg.

Rabbit No. 9—Average tension before operation, 16 mm. hg.; total average after, 14.3 mm. hg.

General average tension before operation, 21.5 mm. hg.; after operation, 18.5 mm. hg.

A summary of the above experiments on the nine rabbits, after a complete excision of the right superior cervical sympathetic ganglion shows:

1. No marked influence on lacrimation. There was an increase in one case immediately after operation.

2. The nictitating membrane was not affected by the operation.

3. A paresis of Müller's muscle, which caused drooping of the upper lid in all cases on the operated side.

4. The average horizontal diameter of the pupil before operation was 7.6 mm. It contracted immediately after the operation, and usually so remained, the average diameter then being 6 mm. In those cases where epinephrin was instilled into the conjunctival sac, it caused a dilatation of the pupil on the operated side.

5. There was no appreciable ophthalmoscopic change in the retina and

choroid. In rabbit No. 4, as seen from the notes, there were certain interesting developments in the iris which I was not able to explain. The tags of pigment undoubtedly developed from the epithelial layer, but what influence the operation had in causing them is a matter of conjecture. While I could not detect deposits on the posterior surface of the cornea a cloudiness of the aqueous was surely present at one time; also there were opacities in the media, which I placed in the posterior part of the lens, as the rabbit's lens is very thick. These opacities later disappeared.

6. There was an appreciable gross change in the color of the iris on the operated side in all cases except one; rabbit No. 3 died 24 days after operation. The longer the animal lived usually the more distinct was this discoloration; and where the eyes were enucleated and placed side by side for closer comparison the change was more decided. About five weeks after operation, changes in the color of the iris were first detected, altho in one case (rabbit No. 8) a suspected change took place in fifteen days, which was more positive during the fifth week. Unquestionable variations in the color of the iris were noted in rabbit No. 4. That is to say, at one time the change was barely perceptible, and at other times the decoloration was decided.

7. The intraocular tension (see chart and table), shows varying estimates, without any uniformity. Taking an average first reading before operation, the right eye was 21.5 mm. Hg., and left 22 mm. Hg. A combined average of all readings after operation (omitting the first reading), on the right was 18.5 mm. Hg., and the average of all readings on the left was 21.2 mm. Hg. This observation would lead us to believe that the removal of the superior cervical sympathetic ganglion lowers the intraocular tension in the eye on the operated side.

8. The age or weight of the animal apparently had no influence in these experiments.

CASES COMPLICATED BY CATARACT OR UVEITIS.

There is another classification of primary heterochromia iridis to be considered, namely those cases in which there is an uveal affection, evidenced by deposits on the posterior surface of the cornea, which may and usually does terminate in cataract. These complicated cases may or may not be associated with the apparent disturbances of the sympathetic. Of the thirty-three cases of iris decoloration associated with sympathetic paralysis, ten cases were complicated with uveitis or cataract.

Lawrence and Hutchinson were among the first to describe the association of cataract with heterochromia iridis, and Fuchs[41] claims priority for first calling attention to the fact that chronic cyclitis with deposits occurred in the lighter eye. He also called attention to the fact that in his series of thirty-eight cases, twenty occurred within the first three decades, nine in the fourth decade, and the remaining number scattered. It was his opinion that heterochromia was usually due to some anatomic difference in the stroma of the iris, and when the retinal layer was affected, [which condition he had observed], it was then due to a chronic inflammation. He often noted that the pupil was larger on the lighter side.

Butler[8] regards the cause as unknown, but when associated with a sympathetic paralysis, the chronic cyclitis may be comparable to the iritis and iridocyclitis which are occasionally seen in herpes ophthalmia, and are usually regarded as trophic disturbances. The same author also describes a train of symptoms which in part are as follows:

The change in the color of the iris may last several years before other complications set in, but sooner or later the patient complains of bad sight in the blue eye. There is never pain or redness, possibly a ciliary blush. There is no associated dyscrasia, altho patients look "out of sorts." Occasionally there is a transient albuminuria.

The eye shows fine keratitis punctata, which soon covers the whole posterior surface of the cornea, altho in other cases it is arranged sector shape. An exudation may develop in the vitreous, followed by opacities of the lens, which are often punctate, and glaucoma is not an infrequent complication. Choroiditis and optic neuritis have been observed. The prognosis is bad. The disease usually begins in youth, and is slow and may extend over a period of years or even decades.

Contrary to the views of Butler, and other observers, Galezowski is of the opinion that the depigmentation is preceded by a chronic inflammatory condition. On the other hand, Malgat regards the heterochromia as due to a difference in the blood circulating in the iris or ciliary body and from a lack of nourishment to the lens, a cataract being the natural consequence. Hirschberg is of this same opinion, but thinks that the defective circulation starts *en embryo* or before the development of the iris pigment. This condition may remain stationary for years, to again become active and cause a uveitis and cataract. Gunn refers to the iris which contains sectors of different colors, and which subsequently regains its color, and he thinks that it is suggestive of an abnormal innervation. Finally Dor[43] thinks that besides the congenital heterochromia (he does not mention sympathetic paralysis), there exists a disease of the eye yet unknown, which begins in heterochromia and ends in cataract.

It is natural to ascribe the formation of cataract in these cases directly to the absence of iris pigment, and also to the influence of the action of ordinary daylight. But Sym has drawn our attention to the fact that albinos are no more liable to cataracts in proportion to their number than are the normally pigmented.

Others attribute the cataracts to the chronic cyclitic which frequently accompanies heterochromia; and as certain other intraocular changes are frequently noted, and as occasionally serious complications follow extractions, it is a commonly accepted cause.

Scalinci regards the cataract as due to changed physiochemic relations with the circulating nutritive fluids or to biologic alterations in the content of the nutritive fluid itself, due to vasomotor paralysis.

Knapp, discussing Ellett's[46] paper on "Heterochromia Iridis, Heterochromic Cyclitis, etc.," was of the opinion that disturbances of the sympathetic system had very little to do in producing these changes (cyclitis). In practically all of his cases, the patients have reacted to the tuberculin test, and in a large number they have done well with tuberculin therapy.

But few writers have attempted to explain the alterations in the iris associated with a sympathetic paralysis; or in other words how a sympathetic paralysis caused an iris decoloration. The investigation of Angelucci on rabbits and dogs offers us a reasonable explanation. He concluded that the eye resents trophic disturbances on account of the influence which the cervical sympathetic exerts on the movements of the walls of the blood vessels (vasomotor effect). It is well known that for a time after the superior sympathetic has been excised, that there is a dilatation of the blood vessels, which in the case of the rabbit can easily be demonstrated in the ears. Later it is followed by a thickening of the vessel wall which tends to contract the lumen. With the weakening of the nutritive changes thus brought about, there is an arrest of development of the eye, and in the case of the iris, there is a more or less pronounced degree of simple atrophy, with its accompanying decoloration.

I cannot find recorded a report of a microscopic examination of a human decolorated iris associated with sympathetic paralysis. Bistis, in his examination of rabbit eyes, found a great reduction in the pigment and a thickening of the vessel wall. The pigment in the anterior layer is much reduced and appeared in small aggregations. The iris stroma possessed no pigment cells, but contained a large number of nuclei which occupy the

place of the stroma cells. These nuclei are round or oval and are situated in a basement substance composed of fibrillary connective tissue. He was also able to detect deposits in the posterior surface of the cornea. These findings, together with a cloudiness of the aqueous and the vessel wall changes, he thinks, are suggestive of an inflammatory condition.

Fuchs was the first to examine a heterochromic iris, occurring in cataracts. In one case he could demonstrate cells on the back of the cornea. There was some depigmentation in the anterior layer, principally of small pigment granules. In the deeper layer there were only isolated remains of the branching pigment stroma cells and these had lost their shape and had become round. These should not be confounded with clump cells found near the sphincter and Bruch's membrane. The retinal pigment layer was normal. The texture of the stroma had entirely changed and the network of the branching stroma cells had been replaced by nucleated cells of a different character. There was no accumulation of nuclei around the blood vessels as is seen in an inflammatory infiltration of the iris. Protoplasm is scanty and occurs around the nucleus like a seal ring. Lymphocytes were only occasionally found and no polynuclear leucocytes were seen. The blood vessels showed a hyaline degeneration; the nuclei were scarce, as were the endothelial nuclei. Complete closure of the lumen was observed.

Lagleyze[45] confirmed Fuchs' observations except there was greater atrophy and more depigmentation in the anterior layers.

AUTHOR'S FINDINGS.

Rabbit No. 1. Interval of eleven weeks and two days between operation and death. The notes show that after enucleation the right iris was "distinctly lighter" than the left, altho a suggestion of decoloration was noted some time before death. Microscopic study of each eye did not show any decided variation from the normal, except in a few of the thinnest sections there was noted an appreciable difference in the general pigmentation in the extreme anterior border layer.

Rabbit No. 5. Interval of five weeks and four days between operation and death. After operation the right iris appeared lighter than the left, but no difference was detected microscopically.

Rabbit No. 8. Interval of approximately twenty-eight weeks between operation and death. There was noted before and after enucleation a decided difference in the pigmentation of the irides. Our findings did not differ materially from those of Bistis, Fuchs and Lagleyze. The greatest changes were noted in the anterior border layer, where there was a general atrophy of the branching pigment cells; this atrophy was likewise present to a large extent in the chromophores of the vessel layer. In certain areas along the margin of the anterior border layer, there appeared to be a disorganization or absorption of the pigment cells, which probably corresponded to the lighter areas seen on the iris during life. The pigment epithelium was unaffected, and there was no sign of inflammation. There was a difference in the thickening of the vessel walls, due to a hyaline degeneration, altho all of the iris vessels are characterized by a thickening of adventitia. We could not detect other marked vessel changes mentioned by other observers, which was probably due to the short interval between the operation and enucleation in this particular animal, as compared to Fuchs' examination of the human heterochromic eye.

Rabbit No. 4. Interval of thirteen months and twelve days between the operation and death. Before operation there was a noticeable difference in the color of the irides. With the low magnification the general comparison of the sections showed a marked difference. In the section of the right eye there was a "washed out" appearance in the anterior border and vessel layer with a noticeable depigmentation of the cells surrounding the larger vessels. These changes were especially noted in the middle and upper thirds of the

iris, and to some extent in the ciliary region.

The sections did not reveal any cause for the changes detected during life (i. e., the iris tags and lens opacities (?) described in the notes).

With the higher magnification, the changes were similar to those described in rabbit No. 8, except for an increase in adventitia thickening.

ACQUIRED SECONDARY HETEROCHROMIA IRIDUM.

Cases of heterochromia iridum occurring secondary to some acquired intraocular state are common to all ophthalmologists of any experience. A severe iridocyclitis, foreign bodies (metal) in the globe, degenerative changes of myopia and chronic glaucoma are the common causes.

COMMENT.

Those who have studied the literature of heterochromia iridis, or even casually glance over the many reports and discussions which I have very briefly collected, must have been impressed with the vastness of the subject and the lack of unity of opinion of the many authors. I, therefore, with trepidation, hesitate to express an opinion, unless substantiated by facts, and unfortunately in this character of investigation, "cold," positive facts are very few. I shall then confine myself to a systematic arrangement of the cases and causes of heterochromia, and express my personal opinion only where experience warrants it. I do not feel, however, that the last word on heterochromia iridis has been written, yet we do know a great deal concerning it.

I firmly believe in the influence of heredity and with the subject under consideration, I am convinced that in a proportionate number of these cases certain tendencies are inherited which cause a difference in the color of the irides. This statement especially applies to the cases in which there is not even the suggestion of any alteration of the cervical sympathetic system. In this country, where our people are not only a mixed hue, but of many nationalities, a proportion of our fairly numerous cases of heterochromia are not pathologic specimens, but simply "freaks" of nature.

Regarding the inheritance of sympathetic paralysis, I believe that its cause may be transmitted, and its manner of producing heterochromia is similar to any other form of congenital sympathetic paralysis, including those of traumatic origin (forceps deliveries). Assuming then this sympathetic disturbance in fetal life, it would not be difficult to explain the arrested development of the iris pigment on the involved side; and we could suppose the changes in those cases occurring in early life, where the iris pigment has developed. These changes can only be explained by nutritional disturbances of trophic origin—first a vasodilation, then a hyaline degeneration of the adventitia, and finally a contraction of the vessel lumen.

The great number of clinical reports show that the difference in the color of the irides to have taken place within the first few months or years of life when the pigment cells were young and apparently easily absorbed; on the other hand I have not found a record where a sympathetic paralysis in the adult produced by trauma or operation, ever caused iris depigmentation.

A chronic uveitis (deposits on the posterior corneal surface), is often recognized in association with heterochromia with or without an accompanying sympathetic paralysis. Many such cases may have escaped close observation. It is claimed that the lighter iris renders the eye liable to a chronic cyclitis, while others are equally sure that the cyclitis precedes the decoloration, in fact, produces it. In support of either opinion, we have no real proof.

From our clinical observation and experimental study the corneal deposits which often accompany the heterochromia should be regarded as a symptom of disease, and where a sympathetic paralysis is associated, it may properly be reckoned as the cause, pro-

ducing the passive hyperemia of the iris and ciliary body which Sym and Scalinci describe. Precipitates have been found on the posterior surface of the rabbit's cornea, and I have observed a turbid aqueous after an excision of the sympathetic ganglion, and if we could at will observe our clinical cases, I believe we would find similar changes at some time.

To my mind there is much to be said in favor of Scalinci's theoretic consideration of the cause for these precipitates and the formation of cataracts. He maintains that there are abnormal substances which percolate thru an abnormally pigmented iris and ciliary body, due to vasomotor paralysis. The normal aqueous does not contain albumin, but when the anterior chamber is emptied, that which is then formed contains it, and fibrin may be demonstrated. This rapidly formed fluid is regarded as a transudate from the superficially placed vessels in the ciliary body, rather than a secretion of the body itself, and it is produced by a lowering of the intraocular tension. This change may account for the cloudy aqueous and precipitates noted in rabbits and for the precipitates seen in man.

The following ocular changes have been produced experimentally: First a decoloration of the iris (Bistis, Metzner, et al.); secondly, a cloudiness of the aqueous (author); thirdly, the formation of corneal deposits (Bistis), and lastly, uncertain lens opacities. The experiments have not been continued long enough to note more decided lens changes, in fact it might take years for them to develop, far beyond the natural life of the rabbit.

This, however, does not explain the other type, in which there is no evidence of a sympathetic alteration, and yet clinically we have the same picture, namely heterochromia, precipitates, and finally cataract.

It is as Dor expressed an unknown disease. It may and usually does begin in youth and have the train of symptoms described by Butler, but hardly as severe and usually without the severe complications. From the investigations of Fuchs and others it is not a true inflammatory type of disease, such as iritis or cyclitis, and its precipitates may be produced from the same type of passive congestion which takes place in sympathetic disturbances. The origin appears to be in the vessels themselves, a type of sclerosis with obliteration. Whether or not this vasomotor disturbance is of trophic origin due to a sympathetic alteration without external evidence, is only a suggestion which other investigators of more original thought might consider.

In regard to the formation of cataract, it also appears that its origin is especially due to a lack of nutrition or to changes in the aqueous.

Finally our investigations have led us to make the following conclusions:

(1) That the difference in the color of the irides should be called Heterochromia Iridis.

(2) That in a small number of cases it is inherited.

(3) That in all other cases it is a symptom of some abnormal ocular state.

(4) That in a large percentage of the cases, a paralysis of the cervical sympathetic is the responsible cause for this heterochromia through its trophic disturbances. This paralysis may be inherited.

(5) That besides a congenital heterochromia there is an eye disease of unknown origin which begins in heterochromia and ends in cataract.

In closing I wish to acknowledge my debt of gratitude to Dr. G. Bachman, professor of physiology in the medical school of Emory University, in whose department our experiments were conducted. His advice was valuable, and the abstracts which he made of the foreign journals greatly facilitated the preparation of this paper.

SYMPATHETIC IRIDOCYCLITIS AND POSSIBLY RELATED PROCESSES IN OTHER PARTS OF THE BODY.

D. F. Harbridge, M. D.

PHOENIX, ARIZONA.

This argument supports the idea that the essential causative agent of sympathetic ophthalmia may exist in the body outside of an injured eye, and be transmitted through the blood currents. Microorganisms entering the exciting eye through injury might become established elsewhere in the body. Submitted as a Candidate's Thesis to the American Ophthalmological Society.

It is a fact accepted by most observers that sympathetic iridocyclitis is dependent upon a chronic plastic uveitis of the first eye. Preceding the fibrinous inflammatory process, the capsule of the eyeball must have been opened; usually by trauma, occasionally by an ulcer, or by operation, such as for cataract or iridectomy. Certain cases, however, have been reported in which the so called typical findings were present, the capsule not having been opened, following certain intraocular growths.

In my opinion, these dogmatic statements should be regarded circumspectly, for the reason that, while the establishment of a sympathetic iridocyclitis may require the occurrence of these events, it must not be overlooked that they are only events in the process, for underlying there is an agent inaugurating these changes. The agent may be a toxin or bacteria, specific in nature, or of special affinity for uveal tissue.

Clinically, sympathetic iridocyclitis shows no characteristic features to differentiate it from so called idiopathetic or nontraumatic iridocyclitis; that is, as regards involvement, cause, and end results. Those of known origin, due, as for example, to focal infections, syphilitic, or tubercular invasion, are particularly difficult of discrimination. Histologically, there may be specific differences.

This contribution was suggested by a recent experience which recalled to my mind the only case of sympathetic iridocyclitis which has occurred in my own practice. I have, of course, observed several cases of so called sympathetic irritation. That is, certain evidences of irritation were present in the fellow eye, but prompt removal of the injured eye was immediately followed by a cessation of these signs. In view of what is about to be stated, it is extremely doubtful whether they would have actually developed into cases of true sympathetic iridocyclitis.

One frequently encounters instances where trivial injuries to one eye, such as a small particle of foreign material on the cornea, will entail considerable irritability in its fellow. May not the irritability in the fellow eye, following more serious injury, frequently partake largely of this character? Clinically we have no means of determining, def-

initely, beforehand, whether the sound eye will or will not develop a sympathetic iridocyclitis. If we wait for frank evidence, the pathologic changes are already established, and it is too late. On the assumption that an eye is dangerous to its fellow, we enucleate; likely we save many, but it does not seem logical to believe that had we not interfered surgically the sound eye would have inevitably been lost.

Comparing my earlier experience, to which I have alluded, with the following case history, I felt I had a more or less common ground in explanation of the two conditions. I was deluded enough to feel that, in a measure, they were original. They were original theories to me, and yet, upon more complete examination of the literature, they seem "strangely familiar."

A man, aged 29 years, with a severe plastic iridocyclitis, had vision of fingers at three feet. Precipitates were present on Descemet's membrane, and the aqueous and vitreous were cloudy. The pupil was small, and atropin failed to tear loose all adhesions. Three years previously the patient had had a similar attack in the same eye. About the time the inflammation began to subside the left eye showed marked signs of involvement; lowered vision and interference with accommodative power, ciliary injection, precipitates on Descemet's membrane, etc.

His general health was excellent. Wassermann, complement fixation for gonorrhea, as well as tuberculin test, made by Dr. Watkins, in the Phoenix Laboratories, were negative. Searching further, two suspicious teeth were discovered, and radiographs showed apical abscesses. Removal of the teeth was followed within ten days by practically complete recovery. The iris of the right eye remained attached at three points.

Doubtless similar experiences have been observed by others, yet the history presents a feature which may merit emphasis. Clinically, at least, there are certain points of similarity between this history and that of sympathetic iridocyclitis. Pathologically, this similarity may not be so striking, and yet it seems to me there are possibilities of something in common between the two conditions.

On January 25, 1912, T. R., colored, aged 56 years, was operated upon for cataract in the right eye. Two weeks later a discission of the capsule was performed. Later he was discharged, with good pillars to the coloboma, and no incarceration of the iris. A convex spherical lens gave him a vision of 6/9. Four months later he returned, the eye sensitive to light, ciliary tenderness, slightly hazy cornea, V = 6/20. In the fellow eye the lens was cataractous, the pupil small, ciliary injection and tenderness, precipitates on Descemet's membrane, and an infiltration of the iris obscuring its texture.

The attack came on suddenly, and rapidly developed into a severe plastic iridocyclitis. Active treatment was instituted, atropin, sweats, mercurials, large doses of salicylates, subconjunctival injections, salvarsan, and purgation. The condition continued in severity, with periods of more or less abatement of symptoms, until February 1, 1913, at which time he was discharged, with occlusion of the pupil. The eye was quiet, and remained so when last seen, April 19th, about fourteen months after the original operation. Vision in the operated eye remained 6/20, with a spherical +10 lens.

Considering this case in connection with my more recent experience, there are certain features which, at least, seem common to both. This patient had many decayed teeth, foul breath, and persistent constipation. At times he suffered severly with toothache. The question of a radiograph was not considered at that time. Doubtless certain infective foci would have been observed. In placing emphasis upon this point, I do so for the reason that very likely such cases are reported as being healthy, save for the eye inflammation.

Upon examining the case reports by many eminent observers, the statement is almost universally made that, "otherwise the patient is healthy." No statements are made regarding the condition of the teeth, tonsils, sinuses

prostate, or many other possible foci of infection, which in themselves may not be particularly disturbing, yet are of vital importance in the etiology of an inflammation in another part of the organism, whether it be a so called sympathetic iridocyclitis, a heart lesion, or a joint infection.

Reflecting upon my own experience, cases of true sympathetic iridocylitis are of rather rare occurrence. I have observed some four hundred patients with injury to the eyeball, including perforating wounds of the globe, some due to cataract operations, others to iridectomies, but the greater majority due to injury by foreign bodies. In a percentage of this latter class the foreign body remained within the globe. Most of the injuries resulted from copper mine accidents, and those incident to the iron and steel industry. Not in a single instance have I observed another case of sympathetic iridocylitis. In some of the cases, there was present some irritability in the fellow eye, but it entirely subsided with the quieting of the injured eye. In a small percentage the injured eye was severely damaged, and as a matter of safety the eye was removed.

Clinical and laboratory observations have been made evolving many familiar theories regarding transference of the inflammation from one eye to its fellow. It is more than probable that there are elements of truth in each theory, which, if we were able to fit them together, might offer a solution. While it is admitted that certain diseases have a specific cause, yet there are many affections which may have a variety of causes, or at least the source of infection, or agent, may come from one of several foci. The same focus of infection may be manifested in a variety of ways, in different tissues.

In any event, there are few which show onset, development, and cause precisely the same. They are modified by many conditions dependent upon individual characteristics and organism metabolism. Having these facts in mind, are we justified, in view of present knowledge, in believing that sympathetic iridocylitis is an entity, due to one specific cause? Rather should it not be considered more as a secondary disturbance, due to a local changed metabolism, the source of the agent being in the uveal tract of the injured eye, or perchance, in some other part of the body, a part of a symptom complex.

Possibly there may be a local focus of infection at the point of injury, but can it be successfully stated that this is always the case, and that this focus is always the cause of inflammation in the fellow eye? Injury of a tissue, particularly if there follows a low grade inflammatory process, leaves that tissue more susceptible to bacterial invasion, or toxic agents, the resistance having been lowered. It is, of course, conceivable that bacteria may enter the globe at the time of injury, remaining resident and more or less quiescent for an indefinite period.

It is likely true in a certain number of cases, but it is equally conceivable that injury to the uveal tissue prepares a fertile soil for bacterial invasion from other foci of infection. The resulting metabolic toxemia finds elements in the fellow eye for which it possesses a definite affinity, the severity of the attack being in accord with its virulence. This seems true, particularly in instances where long intervals are recorded between the time of injury and the onset of sympathetic iridocyclitis.

The fact that in certain cases even following enucleation, at more or less remote times, sympathetic iridocyclitis is established, seems to indicate at least that while we may grant the influence of the injured eye in possibly establishing a low grade inflammatory process, the continuance and increasing severity sometimes after enucleation are more than significant that the "fire" is being fed from another source. This may be from a small apical tooth abscess containing perhaps a strain of streptococci, with a special affinity for uveal tissue. The numerous relapses which sometimes occur during the course of the disease may be accounted for in the same way. The re-

port on sixty-five cases to the Ophthalmic Society of the United Kingdom is particularly impressive on this point. Sympathetic iridocyclitis followed from one to twenty-one years after enucleation. Snell observed one case one hundred and six days subsequently.

In this connection it is well to consider the possibility that, even if an eye has undergone an attack of sympathetic iridocyclitis with recovery, subsequent inflammatory relapses may be the result of entirely different causes, and in no way dependent upon the original inflammation, except in so far that an uveal inflammation renders the eye rather more subject to subsequent inflammation, the exciting cause being in no way related to the original cause.

It is recorded by certain observers, that sympathetic iridocyclitis is more liable to occur in children. I am not in a position to successfully question this, but when one considers the greater liability to industrial injuries of the middle aged male, it rather encourages an adverse view, unless we interpret this as meaning that in a given case a child's tissues are more susceptible to these inflammatory changes. Granting, however, that it is correct, this adds additional support to the theory that focal infection participates in this process, as children are especially susceptible to infections of the nasopharyngeal and oral cavities.

Crediting enucleation in a given case as the means of having saved the fellow eye, seems to me difficult to prove. We remove an eye, believing it to be a menace, yet, in anticipating this danger, we have no clinical or laboratory means of definitely knowing. If the inflammatory changes have once become established in the fellow eye, and the inflammatory process in the exciting eye not so severe as to anticipate complete destruction, and the sight previously serviceable not greatly reduced, such an eye should not be enucleated.

Of course, in the event of complete destruction, as a good surgical procedure it is wise to enucleate, but from my experience in observing three cases, in which sympathetic iridocyclitis was already established in the fellow eye, removal of the exciting eye did not gain anything in particular in the amelioration of the inflammatory changes, nor prevent destruction of the sympathizing eye.

It is difficult to believe that the causative agent of sympathetic iridocyclitis is always resident in the injured eye alone, and that it is the sole etiologic factor to be considered in accounting for the changes in its fellow. If it were, how can those cases be explained in which useful vision is retained in the originally injured eye, and yet the sympathizing eye is lost. It seems reasonable to believe that, if the agent is virulent enough to destroy the sympathizing eye, surely it would produce a like result in the one originally involved, especially in view of the fact that its uveal tissue has already been damaged. Not only is the above reported case history illustrative of this point, but literature contains many similar instances.

These clinical observations are of interest in connection with certain histologic knowledge. Previous to the severity of an attack of sympathetic iridocyclitis more or less discrete granular elevations in the choroid have been observed. In destroyed eyes, which have been enucleated and examined microscopically the uveal tract shows isolated accumulations or elevated formations of proliferating epitheloid cells. The various stages of progression, and more or less isolation, of these nodular formations is strong evidence of their independent development, the agent being deposited at these several points at varying intervals.

If this is correct, the natural medium of transmission would be the blood current. The agent may be in part or wholly derived from the primary injured eye, yet, it seems good reasoning to believe, especially in view of the above clinical experience, that other foci of infection are not only contributing factors, but may be the essential source, by reason of the ease with which the blood stream can convey these agents from one part to another.

The intimate association of sympathetic iridocyclitis with the uveal tract, and the almost uniform accompanying penetrating wound of the eye capsule, arouses interest in contemplating the many perforating injuries to the globe which are never followed by any evidence of this malady. The vast majority of penetrating wounds heal and remain quiet, or at least they do not inaugurate inflammatory changes in the fellow eye. It is inconceivable to believe that they are all aseptic. Doubtless in many instances, likely the majority, the bacteria that find access to the parts are benign, or at east of such a strain as do not possess any special affinity for uveal tissue. If they were immediately virulent at the time of injury prompt destruction of the injured eye would ensue.

If the proper bacteria gain entrance at the time of injury, clinical evidence indicates that certain preparation must take place, as they do not become active for several weeks, and in some reported instances, years. This view is quite in accord with Rosenow's work. Certain strains of bacteria, especially streptococci, have a selective tissue affinity, or they are able to develop this affinity by growing in certain tissue, as, for exampe, injured uveal tissue.

It is quite in keeping with the clinical course of sympathetic iridocyclitis to say that streptococci, or, perchance, some other microorganism, infect the injured uveal tissue of one eye, at the time of injury or subsequently, from some other body focus; and after a certain interval they develop an enhanced ability to attack and destroy similar tissue in the other eye. The time interval is just as much in favor of this as it is in favor of the development of tissue sensitiveness. In view of reported cases of sympathetic iridocyclitis in eyes with intraocular growths this seems especially adaptable as an explanation, the injured uveal tissue affording the necessary cultural media, the bacteria being supplied from some endogenous source.

The results obtained in the experimental work on anaphylaxis have all been on lower animals. The fact that sympathetic iridocyclitis is seen less frequently speaks against anaphylaxis. Surgical precautions would not affect the development of anaphylaxis in an injured eye, but would prevent bacterial destruction of tissues by removing the media suitable for bacterial growth. From the increasing number of eye injuries, and the decreasing occurrences of sympathetic iridocyclitis, possibly as a result of surgical interference, even when the globe is penetrated and tissues destroyed,—if it were anaphylaxis,—we would expect the number of cases to keep pace with the number of eye accidents, but they do not.

A fuller understanding of the nature of sympathetic iridocyclitis demands a more searching investigation for possible related processes in other parts of the body.

NOTES, CASES AND INSTRUMENTS

REPORT ON ONCHOCERCOSIS.

TACITO MOLINA IZQUIERDO.

GUATEMALA, C. A.

The ocular conditions associated with the so called coast erysipelas, which have been described by Pacheco Luna (Amer. Jour. Ophth., v. 1, p. 122), make the identification of the etiologic parasite a matter of interest to ophthalmologists.

During the month of July, 1917, I received from Dr. Pacheco Luna five tumors extirpated from two individuals attacked by so called coast erysipelas and named by him onchocercosis. These tumors had a form similar to that of the seed of a bean (*Vicia faba, L.*), and of equal size or somewhat larger than the same.

Dissecting the outer coat of Tumor A, I found that in the exterior existed a sclerosed tissue, extremely hard; and some nodules of the size and form of a pea which on being cut by a bistoury showed small threadlike fragments of ivory color that were very brittle.

In accord with Dr. Pacheco Luna, and following the method proposed by Brumpt (Precis de Parasitologie, 1913), I submitted the other four tumors to the action of artificial gastric juice, which transformed almost all the tissues of the tumors into a gelatinous matter, and I obtained the following results:

Tumor B. Pieces of the female which united measured about 40 cm. There were neither male nor embryos.

Tumor C. Fragments of the female with both extremities. The extremity of another female. Total of the fractions found, females 60 cm. Two males. Embryos very numerous.

Tumor D. Formed by several nodules. Nodule (a). Female, both ends and pieces of the body. One male of 24 mm. Embryos very numerous. Nodule (b). Extremity of female. One male of 35 mm. Embryos very numerous. Nodule (c). Fragments of the female without extremities. One male. Embryos very numerous. Nodule (d). Female extremities and body. Neither male nor embryos.

Tumor E. Female which with difficulty and patience I obtained entire. Length 32 cm. Neither male nor embryo.

OBSERVATIONS.

The *female* reaches more than 40 cm. in length by 300μ, or somewhat larger — largest diameter. The striae are transverse, well marked. Submitting to hot water, the tumor C. previously treated by the artificial gastric juice, the skin remained separated like a sheath.

The *male*. The length up to 42 mm. Thickness (largest diameter) about 200μ. Two spiculae which protrude almost from the same point, one from one of 180μ, the other of 80μ. The papillae difficult to be seen, the three anal orifices were identified. The tail is always curled up. In one of the tumors, which I examined after those already mentioned, and which also were sent to me, I found seven males and one female. In all I have examined thirteen males.

Embryos, length 250μ, thickness largest diameter 10μ, many even more. In the female with which there was no male, there were no embryos. I did not succeed in seeing any visible "spot."

Ova. I did not find any, but I had before me a preparation of Dr. Robles. They have the form of a lemon with a curled up embryo.

The work of microphotography I did, together with the medical student, V. M. Calderón. The preparations were, two from Dr. Robles, and the other my own.

The tumors have always been found under the hairy skin.

The infected zone of these filarias is in the Pacific region, Republic of Guatemala, between 1,000 and 2,000 feet above sea level.

The following comparative table clearly shows the characteristics of these filarias and their differences from other kinds.

Comparative Table.

FILARIA BANCROFTI. Cobbold 1877	ONCHOCERA VOLVULUS. Leuckart 1893	SPECIMENS UNDER EXAMINATION
Body white opal-like	Body white opal-like	Body white opal-like
Transparent	Sufficiently transparent	Little transparent (before preparing).
Integument smooth	Integument slightly striated transversely	Integument slightly striated transversely. In the preparations striae are more marked.
Body thin	Body thin	Body thin
Thinner at both ends, which are obtuse	Thinner at both ends, which are obtuse	Thinner at both ends, which are obtuse
Mouth unarmed, without papillae	Mouth unarmed, without papillae	Mouth unarmed, without papillae
Male: length 40 mm.	Male: length 30 mm.	Male: length 42 mm.
Width 100μ	Width 130μ	Width 200μ
Tail with tendency to curl in ring form	Tail curved and generally rolled up	Tail always rolled up ring-like
Papillae 3 pairs, post-anal, none preanal	Papillae 3 at each side of anus, and 3 tail ones	Papillae difficult to observe
Spiculae	Spiculae	2 curved unequal spiculae
2 thin unequal ones of 200μ and 600μ	2 curved of 82μ and 117μ	of 80μ and 180μ
Anal opening 130μ from the end	Anal opening 40μ from end	Anal opening 40μ?
Female 8 to 10 cm. long	Female 40 cm. long. (Prout)	Female 42 cm. long or more
Width 240 to 300μ	Width 360μ	Width 300μ
Vulva 1 mm. to 1.30 mm. from the posterior end	Vulva 760μ	Vulva?
Anus 280μ from the posterior end	Anus?	Anus (Female)?
Ova 40 by 23μ	Ova large oval, with a prolongation, pointed at each pole.	Ova ovoid, lemon shaped with a prolongation on one of the poles.
Ovovivipara	Vivipara	Vivipara (Molina) Ovovivipara (Robles)

STEREOSCOPIC SILHOUETTES FOR TESTING ESTIMATION OF DISTANCES.

Capt. Harry Vanderbilt Würdemann.

SEATTLE, WASHINGTON.

These tests adapted, redrawn and translated by Dr. Würdemann were submitted for publication soon after the United States entered the war. It was deemed prudent to delay their publication at that time.

Some time ago there appeared by some foreign author whose name I do not know and in what publication I am not cognizant, a description of a stereoscopic test for binocular vision and estimation of distances.

The plates were later republished and sold by Carl Zeiss of Jena. Photographic copies of these plates have recently been in use by the Examining Boards for Aviators of the Signal Corps of the United States Army. These were in the German language and as their use in this form for this particular purpose did not seem to me to be patriotic, therefore, I

appropriated the unknown author's ideas in toto as the spoils of war. I have redrawn the plates and have translated the lettering into the American language. It seems appropriate for this particular purpose that as the silhouettes were all of German objects that our American aviators will certainly see on the battle line at no distant period, the same objects be reproduced, and therefore, the plate here pictured and described is exactly the same so far as the drawing goes as that in the German and thus I claim no originality whatever in this reproduction and essay.

I had the original enlarged five times by photography and redrew the pictures, substituted for the German legends their meaning in English and had it reduced to stereoscopic size by photo-engraving.

The difference between the lateral centers of each picture in the stereoscopic engraved reproduction varies according to the following:

The distances between numbers 9 and 9 are 66 mm.: between numbers 10 and 10, 68 mm. The objects numbered between these are 1/5 mm. more or less apart. The scale reading 9 for the nearest, 1, 7, 3, 4, 5, 6, 8 and 10. There is a slight variation in the picture to give a certain amount of stereoscopic perception of depth and aiding in the perception of distance.

No. 9 Gate in Lübeck, should seem the nearest, No. 1, Hohenzollern Castle next, then in the following order, 7 Holtenauer Lighthouse, 3 Cologne Cathedral, 2 Wartburg, 4 The Berlin Dome, 5 Lichtenstein Castle, 6 Zeppelin over Strassburg, 8 German Battleship "Kaiser Friedrich" and 10 which is the farthest away, German School Ship "Stein."

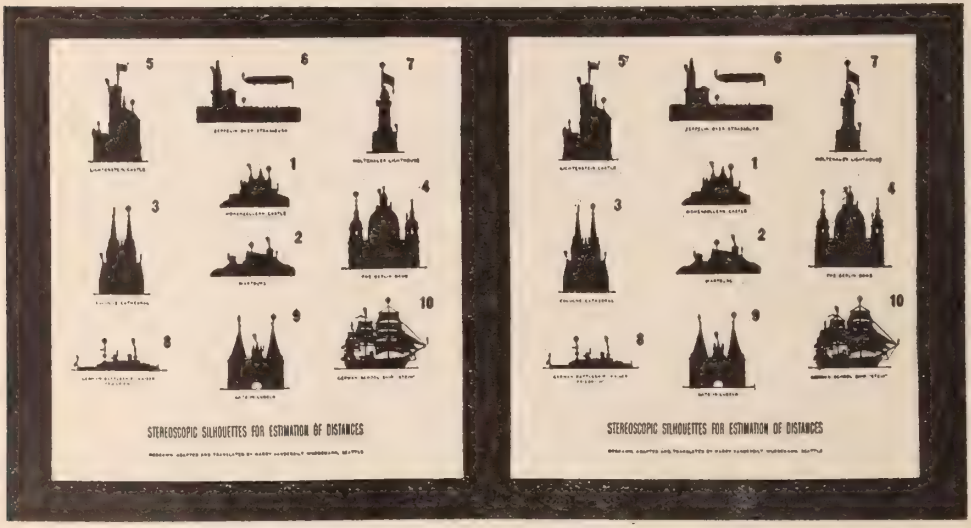

Fig. 1. Stereoscopic silhouettes for Testing Sense of Distance.

This is the most delicate test for binocular vision and for the perception of depth or distance. Any candidate for aviation who does not correctly answer these in the notation and rotation as above given has an imperfect perception of depth and distance and is not qualified for either a flyer or an observer. In civilian practice, the same condition holds good as when the numbers are properly stated there is evident perfect binocular vision. Persons with esophoria or exophoria beyond what may be esteemed the normal condition, i. e., not more than 5° esophoria or 3° exophoria for infinity or 6° exophoria for 30 cm. can not as a rule solve this chart as do those with perfect muscular balance.

GONOCOCCIC DACRYOCYSTITIS.

Dr. Francisco M. Fernandez.

HAVANA, CUBA.

The ocular complications of gonorrhea have been described by numerous authors, some a long time ago, some others very recently; and among these we have described several cases of metastatic conjunctivitis having that origin, and which is by far more common than the variety of ectogenous origin. (Archiv. de Oftalm. Hispano-Amer. v. 17 p. 320.)

On the other hand, the germs liable to produce dacryocystitis are first the streptococci and staphylococci, it having been stated by Wakisaka that the Influenza Bacillus and the Pneumococcus are also common. Less so are the Bacillus Coli, Pyoceaneus, Friedlanders, etc.; as well as some sarcinae, actinomicocydes, and other unclassified bacteria. But the presence of gonococci in the purulent secretion of a case of dacryocystitis is, although not extremely rare, of infrequent occurrence, it being due either to an ectogenous origin, or a metastatic one.

This observation refers to a curious case in which the lacrimal sac was surely invaded by the gonococci, without any involvement of the conjunctiva, the case occurring in a young man suffering from urethritis.

Case X. X., a young man employed as clerk in a store, went into the Benéfica Hospital on the 2d of January, 1919, to receive treatment for his urethritis, and some days after was sent to our ward in order to have his right eye treated, as there was some pain and inflammation around the sac.

We saw the case and there was a typical dacryocystitis, with obstruction of the duct, and much tenderness and redness. After incising the abscess, the purulent secretion was sent to the laboratory. We received a report stating that the case was one of gonococcic origin.

We had a perfect drainage established for the escape of the secretion and after being sure of the cause of the disease, and ordering the best ways to combat it, the patient made an uneventful recovery and was sent back to the venereal ward after eight days without any ocular complications.

THE FRIENDSHIP BETWEEN DONDERS AND VON GRAEFE.

Dr. M. A. Van Herwerden.

UTRECHT, HOLLAND.

This paper consists chiefly of personal letters preserved by Donders. It appeared in Janus, the International Journal of Medical History, the organ of the Dutch Historical Society of Medical Sciences, Twenty-second year, Parts five and six. Translated by Dr. William H. Crisp, Denver, Colorado.

"London seemed quite dead to me after you had left us, for in the first place there was no one from whom I had learned so much that was worth knowing as from you, and moreover my personal intercourse with you had been my very greatest pleasure. I know you too well to fear that you will receive this childishly frank confession of mine in bad part. You yourself must have observed from my entire behavior how inspiring and pleasing your personality was to me. To work with you or more correctly under your ægis would be the fulfillment of a beautiful ideal; in zeal and love of truth at least I might be your equal, and the rest comes, as Shakespeare's Constable says, from God."

With these words the twenty-four year old Albrecht von Graefe reflected the impression which the young Dutch physiologist F. C. Donders had left with him during a joint stay in London in the year 1851. They form the beginning of an animated correspondence which took place between the two men of learning during the years 1852-1870.

In the Graefe Museum in Heidelberg is a collection of faded letters, witnesses to the warm feeling of friendship which for almost twenty years bound the famous Berlin ophthalmologist to our great Donders. We have Donders' personal act to thank for the fact that this correspondence has thus been preserved to posterity.[1]

For the history of medicine this correspondence contains letters of great significance, which I hope to publish later. Regarded from the purely historical standpoint, the opening letter is the most important of the collection. The first experiments with the ophthalmoscope discovered by von Helmholtz in the previous year are described therein, and the instrument which, improved according to his own specification, was to open a new epoch for ophthalmology, is offered for Donders' use. The value of these letters from Graefe is not, however, purely scientific. They speak from one great mind to another, they awake by means of single sentences interwoven with a learned discussion such stirrings of the mind that not only the sympathetic personality of him who wrote them, but also the picture of the friend who received them, arises before our mind's eye.

Between the sixty-seven letters there are lacking those members of the series which would have linked them into an extremely valuable harmonious whole, namely Donders' replies. These have been found neither in the Graefe Museum nor in the possession of von Graefe's descendants. But no one who reads the Graefe letters can doubt that the beneficent, radiant warmth did not come merely from one side.

For Donders likewise the first companionship in London with the colleague ten years his junior was refreshing to heart and spirit. In an infirmary where Donders attended clinics with the Viennese ophthalmologist von Jaeger, there burst in unexpectedly a young man in Alpine costume who threw himself into the arms of von Jaeger. With the words "You belong together," von Jaeger threw young von Graefe "literally into my arms," so relates Donders in the year 1886.[2] "And he had not deceived himself . . . von Graefe was my leader in the practical departments of knowledge in which I had wandered so little, and I on the other hand could furnish him with a number of details from the physiologic side. In this mutual completion there lay a great charm for us both. Those days, in which Graefe revealed all his amiableness of disposition, are among the most beautiful recollections of my life. When, after a few weeks, I left him, he had become as a younger brother whom I admired and loved."

"With great joy did I learn to know the goodhearted Jaeger from Vienna, and especially young Graefe from Berlin, who is not merely a good surgeon and ophthalmologist, but at the same time a meritorious physiologist and a lofty man. He will soon visit you," writes Donders a short time after his stay in London, to Jacob Moleschott, that other friend with whom he remains associated thru a long continued correspondence, this time up to his own death, because Moleschott outlived Donders, while von Graefe, as is known, died in the year 1870, when barely forty-two years old.

Some months after the first encounter, when Donders hopes to come to Berlin without the wish being fulfilled, von Graefe writes: "The idea of working and living in common with you here had become a regular impulse of my life, and in my thoughts I had already pictured in delightful colors our

1. "I should like to bring with me something for the Graefe museum . . . . and in any case to arrange that after my death the letters addressed to me by von Graefe may find their place there," runs a letter from Donders to one of the members of the Ophthalmological Society.

Some of the Graefe letters contain remarks of Donders in his old age. How deeply he felt concerning them after the premature death of his friend is shown by a complete transcript which Donders left behind him. This transcript, committed to me for preparation some years ago, caused me to look up the original letters.

2. Address delivered to the Ophthalmological Society in Heidelberg on the 9th of August, 1886, on the occasion of the conferring of the Graefe medal on Helmholtz.

entire activity. Altho I might have been able to return only a feeble equivalent for the much which I thought to obtain from you, yet on the other hand I was certain that you would lack nothing that deepest friendship and most sincere respect afford. The sum total of my activities appears to me at times quite niggardly and wretched when I hear yours spoken of. While I perambulate in a relatively narrow circle of science and even there stumble all too often on unanswered questions, you wander with certain stride in the broadest and most beautiful fields of human knowledge and leave no spot without plucking some fruit. With such unequal gifts the only thing that I dare to presume to share with you is honesty of endeavor and the impulse to widen the boundaries of positive knowledge to the extent of my powers."

In every direction it was a period of exuberant growth in the lives of these young men of science. How necessary to keep one another informed not merely of the daily surprises in the scarcely explored fields of physiology and pathology, but at the same time concerning their deepest experiences! Along with the recollections of short meetings in Utrecht, in Berlin, Heidelberg or the Alps, with the longing to see one another again, there predominates the friendship of man for man. In relation to friendship, scientific interest — however important it may be and however large a part of the correspondence it may take up—occupies the background.

"Your letter came like a beautiful echo of bygone days and in the midst of our deafening everyday life again awakened their shining image before my soul," writes von Graefe after a visit of Donders to Berlin. "There is always, who could deny it, an element of melancholy sadness in this retrospective view of a happy past; but that is succeeded by a juster mood of pure delight, for the past truly belongs to us, the inviolable treasure of living memory. Only he who is unfaithful to himself loses also with himself the past. Thus will I gather to myself as an inalienable possession the days which were lived with Donders, and be grateful without complaining against my fate. If you will leave me a place in your heart which perhaps I obtained without deserving it, I shall hope that past days were only the first chapter in a book of friendship whose story is without intrigue, but nevertheless and even on that account of the profoundest interest to those concerned."

In 1856, when von Graefe hopes to journey to Utrecht, he writes to Donders: "Do not be terrified by these words, because it really sounds as tho I would occupy your precious time with the whole of my inquisitive soul and fasten myself on your few hours of leisure with the whole weight of my questions. Believe much rather that along with the impulse to pump you dry there also lives in me so much respect for your physical and psychical welfare that my tormenting you will not be allowed to overstep a certain limit. It is, of course, sad for you to have to give up so much, but that is merely the disadvantage of the possessor in the democratic state of Science, to be held up by every needy fellow. So adapt yourself to your fate and from your friendship for me, precious and on my side undeserved as it is, derive resignation to tolerate the Berlin tormentor for an October week in Utrecht."

And in the year 1859, when von Graefe urges Donders to undertake an Alpine journey with him: "We really have much to exchange and aside from all ophthalmologic shop, it is after such a long separation only a natural need of the soul to influence one another again in more immediate fashion. I am quite aware that in this intellectual intercourse I am the recipient, and this even more than was formerly the case, since my strength has been broken by a number of adverse circumstances. But all that does not matter, one does not weigh and calculate, one follows one's inward attractions."

The feeling that, in relation to Donders' great figure, he was always the subordinate, the recipient in relation to the donor spirit, never left von Graefe even in later years, even at the time when his fame in broader circles exceeded that of Donders, and when pu-

pils and patients streamed to him from far and near.

"I brought nothing to Berlin but the burning wish to see you again soon, very soon, and with your two letters you succeeded in inflaming this desire," writes von Graefe a year later: "It is really an absolute intellectual necessity to me to be further associated with you." Your great saying: "To know is useful to us, but to learn is bliss," descends as a judgment upon my soul (fällt mir mit Centnerlast auf die Seele). How I feel with you in this,—but oh! poor I am destined "to know nothing right and to learn nothing more at all," while you surrender yourself to "the unspeakable delight" and by your learning continually bring knowledge to others. What remains for me . . . but to rejoice at your flight and with the fancy of friendship to occasionally imagine myself flying a little way with you!"

"I must *see* you soon in one way or another," we read eight years later. "Altho my life has really contained nothing special—with the exception of New Year's Day[3]—yet almost every day it seems to me as tho I had something to tell you. That is the true measure of mutual attachment, that we gather for each other, involuntarily—even tho mutely—the small blossoms which every day strews upon our path. But at times we must speak. Let us attend to this in our short life as far as in us lies." And again a year later: "Yes, those were truly beautiful days, beautiful hours when you slept under my roof . . . To create for ourselves as many noble joys as possible—is not that the only natural defence against the eternally recurring vexations of life? Vexation at circumstances, vexation at the human heart and at times also at one's own strength and worth—'Ergo bibamus,' 'Come soon, very soon!!' "

"How incessantly I long to see you! Your few words concerning faithfulness strike like lightning into my heart or rather they sink therein like a ray of sunlight. One feels only too deeply, the farther life unfolds itself, that faithful mental communion is not an attribute of human relationships, and that the proud joy of sharing heart and thought lovingly with one another, of serving and belonging to one another, languishes ignominiously beneath the parasitic exuberance of the ego. And the oases in the desert of this tendency lie so far apart and so scattered, that we can only attain them in fugitive moments. May heaven always preserve at least the thirst for them within us, for in this thirst, however little it may be quenched, lies the experience of that which we need in order to become real human beings."

After a visit of Helmholtz's, von Graefe writes to his Utrecht friend: "Helmholtz visited us in Berlin and greatly rejoiced us by his presence. He honors you quite as you deserve, and to me this was still another important point of attraction in the inventor of the ophthalmoscope."

But the great respect which speaks from the Graefe letters will never cloud his independent judgment, never restrain him from giving counsel in perfect frankness. When, in refutation of a German colleague, Donders sends a vehement essay to von Graefe for publication, the latter replies: "If I did not express my views concerning it, this would appear to me either forgetfulness of duty or cowardice; the former would be an injustice, the latter petty. The name of Donders stands too high with me to see him take an attitude toward S. which in the eyes of the uncomprehending multitude is interpreted as that of common polemics. He who as man and savant occupies such a place of honor does better to keep his hands clean of the filth which baser minds accumulate abundantly around them . . . so you will not be angry with me if I satisfied a necessity from which I could not detach myself because to me your person is so sacred that it worries me to see it in any way defiled through the perfidy of a baser mind."

In what spirit Donders' answer to this letter dated 21st November, 1853, was couched appears from the few

words written by him upon it with trembling hand when in his old age he read it through and revived its memories. "Splendid letter" we read there. It is thus very probable that Donders did not disregard the counsel of his youthful friend. Toward another friend it was Donders himself who at the same period was always the restraining, the deliberate counsellor. During this period he writes no letter to Moleschott without protesting against his vehement essays.[4] From both correspondences may be learned in what frank and sincere relation these men, whose friendship was founded upon deep respect, stood to one another.

Until the year 1862 the correspondence with Donders is only interrupted by the exchange of visits, visits which, as already appears from the quotations, leave behind a treasure of memories. Even small railleries are not lacking after the Berlin visit. The preparation of a cysticercus has to be sent to Utrecht. "How is the poor little animal to reach his Utrecht home? Shall I risk sending him through the post carefully packed, or with my own hand commit him to your envoy, as something which exercises a decisive influence upon the weal and woe of mankind?" And in the next letter: "With this little sheet are despatched to you two copies of the Archives (Arch. f. Ophthalmol.) and also—woe is my orphaned desk—that beautiful decoration the cysticercus. May he go and prosper and bring luck to your house, and to your hand a blessing for very many, many children of men."

We can imagine how much Donders, always a welcome guest in the parental house of Graefe, sympathised with the friend who in deep mourning over the death of his mother wrote him the touching words: "In spite of all the help that had been called in from here and outside I saw what was dearest to me on this earth become paler and more lifeless from day to day, and on the twenty-second of November was obliged to kiss for the last time the hands which since birth had heaped so many kindnesses upon me. In a short hour on a cold winter day I buried a long sunny season and now I wander about motherless before the closed door of my paternal house, impotent to conjure from the lifeless walls all the love which dwelt therein."

In the clinic and the workroom Graefe's earlier activity again revives. It is the time of the first glaucoma operations, that discovery thru which he shielded hundreds of contemporaries and millions of posterity from blindness. His leisure hours between his tense daily work, and also his vacations, were devoted to scientific investigation or to working up the wealth of clinical material, which from the year 1854 was described in a first ophthalmologic journal founded by himself (today well known as the most eminent in this field). It was the man of scarcely twenty-six years who brought this plan to realization. Already in the course of the first year, at his request Donders and the Viennese .ophthalmologist von Arlt were added as associate editors.

In the year 1861, when after his betrothal to the Danish countess Knuth a sunny time promises to begin for von Graefe, and he joyously hopes for a speedy meeting with Donders in Heidelberg, there follows forthwith on the way to Heidelberg a serious illness in Baden-Baden, which for a while interrupts the correspondence. Donders personally visited his ailing friend. In touching words he himself gives a description of this visit: "Poor friend," said I, pressing his hand. "Yes, poor friend," replied he and added: "I occupied a whole hour in giving up all my illusions. But now I am all right again. Tell about Heidelberg." And when, moved by this "one hour", I did not immediately respond to his desire, he seized a book that lay by him, it was Goethe, and pointed me to the words whose deep meaning had so often struck us on Jaeger's test card: "One cannot too

3. On which day in 1868 von Graefe's only son was born.
4. For the correspondence between Donders and Moleschott see Janus, 1915, vol. 20, pp. 174, 409.

early experience how dispensable one is in the world."

At the end of June, 1862, the convalescent was for the first time in a position to write personally to his friend: "Yet how immeasurably great is the contrast between what after the long difficult time my heart holds for you and what my hand, at the present moment still weak, is able to accomplish . . . In the sunshine of recovery after a hard desperate illness, all good and noble impulses, which life alas so easily represses, spring up with original power out of the human heart; we feel the impotence of seeming possession and the value of real possession better than in healthier days. We are drawn to those in whose hearts we feel that we have a home."

And a short time later, when Donders has submitted to him his work on astigmatism: "Ought I to deny how proud I am over the dedication of Astigmatism? It is in the first place the honor which you have bestowed upon me, in that such an author has put my name on his title page, and then the joy which I derived from the contents of the work in which your creative and so happily organized mind instructs us in the most unmistakable fashion; but lastly it is the touching friendship and love which you express to me in the introductory words, through which so entirely after your own fashion you succeed in elevating me and spurring me on. On this occasion I again felt and knew how much more precious it is to be recognized and befriended by one whom we love and respect than to be praised by the multitude, even by our so-called colleagues.

"The true scientific sense, which has its roots in the thing itself and finds its starting point and objective in the striving for understanding, has been, we will freely confess, the portion of very few men; almost all of them snatch only at enrichment in honor and reward, and regard thru other and smaller eyes the things which did not originate with themselves. But for this reason the spirit attaches itself more firmly and intimately to the forms of those within whose bosoms a higher impulse dwells and whose spiritual life has broken for them the road to higher spheres. Thus do you, my dear friend, prosper on in your sphere with vigorous wingbeats, and if it can cheer you to animate and impel others by your own motive power, be assured that I shall follow you unceasingly and always gather up gratefully the seeds which you scatter so generously and prodigally. Although I always have a longing to be in communication with you and to receive new impulses from you, at this moment this desire has reached its highest point. What have I not gone thru since you sat at my bed and read in my eyes that I believed myself to be taking a last farewell from you?"

In the summer of 1863, after a preliminary convalescence, von Graefe was married. Donders was a witness in Berlin of the first happy years of married life. Companion in joy and sorrow, he received the enraptured words of his friend concerning the first little daughter: "If you could only once see her, how friendly she looks around and how agreeably she comprehends life. It is true that these are studies and observations of perfect bliss which every feeling human being experiences in similar fashion, and yet each one surrenders himself to the illusion that he is illuminated by an altogether special ray of luck."

And when after a visit of Donders in Berlin in the year 1865 a little daughter dies, the touching plaint reaches him: "Our child is not dead . . . but hope is. The evening hour which you passed with us was the last gleam of light . . . Tears, only tears, still fall on the dear pale mouth. Commiserate with the friend in whose soul everything seems very dark and in his misfortune keep your thoughts true to him."

"The loss of my child came home to me terribly," writes von Graefe in the same year, "and the days in which one thread of hope after another was torn asunder were for myself a pitiful lingering death . . . If one is smitten by misfortune and cannot fully regain his equilibrium, neither is it given to us at such times to irradiate others har-

moniously; although we yearn for sympathy and help, we sink back continually into the gloomy key-note and shut ourselves up in ourselves. To this must be added that he who is sorely afflicted appears to himself as tho infected with a contagious disease; he also fears to infect and depress the soul that is healthy and erect, and the more so the closer he stands to him."

When a year later a new child is to occupy the empty place, von Graefe expresses the wish that Donders should come as godfather: "You had gone thru that terribly sad time with us and, with the true heart of a friend, had in such a way shared with us all our deep woe, that we thought you ought still to have a special association with the little newcomer who seemed destined to soften our grief." The thought of tieing a bond between Donders and his children is awakened anew as the years approach when Graefe's tottering health renders probable an early end—a distinct indication how highly von Graefe placed the character of his friend, to whom after his death he wished to intrust the guidance of his son: "It would appear to me almost presumptuous to disturb you in your rest on account of this little citizen of the world. But you must allow us—in case you do not bring to life the incredible beauty of an actual visit—to register you as a witness and place you in closer and lasting relation with our little offspring. You must also promise me at once on this occasion in case I should not live to see it, to be a faithful counsellor to him in his studies . . . If you come, I should in any case take care that in the succeeding days you will be compensated, by something ophthalmologic of interest, for the insignificance of the little man who calls you hither.

Many a remark in the correspondence is also devoted to the family life in Utrecht, which von Graefe so often witnessed. After the receipt "of a charming photograph" of Donders' daughter in the year 1867, von Graefe writes: "From your daughter's eyes your intellectual nature is so completely reflected. Shine on in full vigor, happy father! and joyfully drink into your own soul your youthful mirrored image! To beget life and from the created one to receive again new life, that is the blessed reciprocal arrangement of things in which the mortal feels himself immortal."

Scarcely three years later von Graefe, seriously ill, received the news of the death of Donders' only daughter[5]. Laboriously guiding his pen he wrote to his friend from the sick-bed: "This day on which I opened the unspeakably painful message will endure to me also as impenetrable night, for your happiness in your child was one of the best lamps of my life; so happily was it reflected over to myself when I saw your dear soul so completely filled by it . . . In vain I ask my wife to give me your letter once more. She sees how deeply I am suffering and refuses . . . Oh could I but convert your note into a feverish dream."

On the same day von Graefe writes in his last letter to Arlt in Vienna[6]: "What do you say to our Donders' frightful misfortune! . . . It is horrible, for he lived only in his Marie, on whom he focused in a certain measure his whole ego, not merely natural but also intellectual.. To me also the news was a heavy blow. I was fairly convalescent, now I have only to think about it, how unhappy, how plunged into deepest night is the man whom I know and wish to know only as irradiated with sunshine—and I am sure of an attack of fever. If among those who are dearest to him one sees only misfortune after misfortune break out, one asks himself at last, where then does the motive lie so to love and foster life? But enough, my cerebrum still totters."

The same thought, that the man whom he had learned to know progressively as a shining hero in life must not be broken by suffering, predominates in the letter which von Graefe

5. Married in the year 1869 to Dr. Th. Engelmann, later professor at the University of Utrecht 1871-1897, and of Berlin 1897-1909.

6. Von Graefe's letters to Ferd. von Arlt are published in the Wochenscrift für Therapie und Hygiene des Auges, vols. 12 and 13.

writes to his friend eight days before death: "The slightest thought thereof (of Donders' suffering) called all too vividly to my memory from bygone time the chain of all your expressions of happiness, beginning with our last talk on the walk from Inselbad; I saw you before me radiant with that gleam of happiness which I had fancied I should never have to see extinguished in your features, I heard your words concerning the intellectual character and entire activity of her who belonged to you so closely, and I was too ill to remember with any calmness the present state of affairs . . .

Von Graefe's death in the year 1870 brought the correspondence to an end.

The friendship of twenty years duration between Donders and von Graefe, interrupted by no discordant note, led —by reason of its fruitful mutual influence—to consequences which extend far beyond the bounds of the individual existence of these two great men.

What a deep, far-reaching influence proceeded from Donders, that with the flight of years the friend who had the world at his feet continued unchanged in his faithful reverence!

The man who as son-in-law was later to occupy such an important position in Donders' life, Dr. Th. Engelmann, also experienced the power of this influence when at his entrance into Holland, he wrote in the year 1867 to the Heidelberg anatomist Henle: "However great the leap from Germany to Holland, however radical the changes which one must allow to enter into his way of living, however unpleasantly above all the foreign language greets one at first, still even a nature which is little capable of adaptation must soon feel at home here if such good fortune falls to his lot as is that which intercourse with Donders affords. The spell which the personality of this man exerted upon me from the first moment, a spell whose beneficent fetters, as I perceive, will not easily fall away, causes me almost to forget that I am in a strange land."

Truly as a radiant figure did Donders in the broadest and most favorable sense dominate his environment.

SOCIETY PROCEEDINGS

COLLEGE OF PHYSICIANS OF PHILADELPHIA

February 5th, 1919

Col. Wm. J. Taylor,

PRESIDENT

Concussion and Contusion Injuries of the Eye in Warfare.

Lt. Col. George E. de Schweinitz discussed some of the results of these injuries, and the pathogenetic problems which they present illustrating his paper by diagrams and water colors showing fundus lesions. This paper will be published in full in a subsequent number.

Discussion: Captain George H. Cross: The markedly interesting picture presented in the ophthalmologic service in Hospital No. 11 at Cape May was the enormity of the hemorrhages or involvement of the fundus which masked temporarily the true condition. A long time after the injury there would be the appearance of a rupture but it was difficult to tell whether there was atrophy or rupture of the structures beneath. We had three cases of, so-called, "holes" in the macula, all due to injury of the skull and not directly to the eye.

We have at the present time another type of lesion in the case of a soldier with a piece of shrapnel about a centimeter square in the median line of the sphenoid, which penetrated straight in without injuring either eye

directly, but the visual fields are most unusually contracted. Externally the eyes are perfectly normal. In other cases the missile has struck the antrum injuring the orbital rim and floor. While the eyeball shows no external evidence of injury rare fundus conditions are found internally. In some cases the orbital rim and parts of the bony wall have been torn away but without injury to the eyeball itself, except displacing it from its normal position. Examination shows that there may be only light perception, with this peculiar condition of the fundus; in others a surprisingly large percentage of vision is retained. In one soldier the foreign body, while not injuring the globe directly, struck the rim of the orbit, traveling along the nasal side, finally landing in the orbital fat. The patient stated that when struck he became temporarily blind in both eyes; in three or four days he began to recover vision in the right eye, and when he arrived at Cape May the picture was that of a fine granular pigment in a triangular area below the disc, with no other evidence of injury. There was a perceptible diminution of vision in the field corresponding to the pigmented area noted in the fundus, but no scotoma was found, and no other pathologic condition.

Re-education of the Blind Soldiers.

Lieutenant Colonel James Bordley, Director, Red Cross Institute for the Blind, Baltimore, Md.: In an investigation of the wage earning pursuits of the civilian blind it was shown that the vast majority of the 85,000 blind in this country are dependent, in part or in whole, upon their friends, or the State; that in 100 cities 43 per cent. of the professional beggars are blind people; that the average wage of conscientious, willing, working blind men is about $4 per week, and that of the same type of blind women is about half as much.

Blind people have a very definite economic value when properly trained. More money is wasted each year in foolish charity that would be required to train and place our whole blind population. Few people know that there is not a single school of the vocational training of the adult blind in the United States, that there never has been devised a scientific scheme for their education and training and that not a single normal school trains teachers for the blind. The medical profession is not altogether blameless for the mental deterioration of many blind people; thru mistaken sympathy the blind are kept in ignorance of their real condition. The attitude of the family is often a most serious drawback to their occupational development.

The attitude of the public is responsible for much of the trouble of blind people, and it was primarily to overcome this attitude that St. Dunstan's in England, and Evergreen in this country were opened. They are not schools in the narrow sense, but rather, universities where the blind are taught hope and courage, trades and professions, ambition and success. The men there are not "poor dear blind boys," but strong, resolute, normal men expecting to win. The courses of instruction at Evergreen are divided into recreational, essential handwork, and vocational.

The blind man has more difficulty learning to play than to work, and for this purpose music, dancing, bowling, swimming, gymnasium exercises are available as indoor activities, and field events as outdoor sports. Included in the essential handwork is typewriting. Another essential study is the raised dot type of the blind—Braille. The usual schemes for developing the sense of touch are taught. As occupations of profit there are taught bookbinding, telephone operating, massage and other industrial and commercial subjects.

Included in the commercial course is the application of an experimental store, the advance agent of a chain of stores to be operated by and in the interest of our blinded military men. The experimental store in size, color, shape and fixtures is the model that has been adopted for all the stores, and from this experimental store at Evergreen the

men will be transferred to our experimental stores in the business section of Baltimore. These stores are to be called "The Victory Stores," meaning the defeat of gloom, despair and affliction of the blind man himself. Our plan for teaching industrial work for the blind was evolved by our having an industrial engineer make a survey of industry and by a process of elimination it was readily discovered what jobs the blind could best fill.

Research Work on the Problems of Aviation.

Major Walter B. Lancaster, Boston: For the study of the problems of flight the visual function may be divided into the purely sensory or percipient, the adjusting mechanism, and the psychic side of vision. Sensory functions withstand the strain of asphyxiation and fatigue without breakdown. Under this head are the retinal functions of light sense, color sense, form sense. The adjusting mechanisms are three: Fixation, focusing, adaptation to light. These are rather complex functions, and are likely to break down under strain; whether they will or not in a given case depends upon whether any defect is present, and on how well the defect is compensated, some defects being better compensated than others. To insure the best compensation the mental and physical conditions must be maintained at their best, hence the importance of the "care of the flier."

The psychic side of vision includes stereoscopic vision and various matters of judgment and discrimination based on visual perception. They are not much affected by asphyxiation and fatigue. Investigations are now being carried on regarding stereoscopic vision, and other methods of estimating distances at long range, as to light sense and adaptation, as to accommodation speed, and as to the relative value of different ways of measuring heterophoria.

Major Meyer Wiener read a paper entitled The Army School of Ophthalmology, which will be published in full in this Journal.

ROYAL SOCIETY OF MEDICINE

Section of Ophthalmology

February 5th

Mr. W. T. Holmes Spicer, M.B.

President.

Retinal Changes Following Injury.

Mr. A. C. Hudson exhibited a case of retinal degeneration following the entry of an intraocular foreign body. The appearance seen was that of folds in the internal limiting membrane of the retina, as he took the location to be such. Some of the lines passed in front of certain retinal arteries; they also had a faint stippled appearance, both factors supporting his view that the seat was the internal limiting membrane of the retina. He did not regard them as folds in the retina itself. He thought they were pathologic.

The optic disc showed signs of having been edematous, and he thought there had been edema of the whole retina and optic disc. He had seen another instance in a case of retinitis pigmentosa, the folds in that case having occurred as a result of traction in the retina; likewise in a case of contusion of the whole macula. In this last case the retina appeared to be absent, except the portion which was represented by the double contour line. He regarded the lines as exactly analagous to the peculiar double lines to be often seen in the posterior capsule after cataract extraction; and to those seen in the cornea in striate keratitis following injury, again due to the folding of a thin elastic membrane, Descemet's.

Discussion—Mr. J. Herbert Fisher said that supporting the idea that there was here a new formation, was the fact that the man was definitely blind in his remaining eye for a considerable time after he was hit. That suggesed a definite lesion, probably in the fundus oculi; and as there was ecchymosis on the anterior part of the globe, probably the central edema was considerable.

Mr. A. W. Ormond thought the swelling was much greater in the upper than in the lower part of the disc, and he regarded it as pathologic.

Ivory Exostosis of Orbit.

Mr. William Lang and Colonel Donald Armour showed a young man from whom Colonel Armour had removed an ivory exostosis of the orbit through the cranium. Colonel Armour said the surgical problem in this case was one of operative approach i. e., by what means the tumour could be reached and completely removed without doing damage to the cranial or orbital contents, and quite secondarily, to ensure that there should not be much disfigurement afterwards.

After seeing the skiagram, he concluded that the best approach would be through an osteoplastic flap turned over the frontal region, with its base at the supraorbital margin, turning down scalp and bone together. He did so, and that gave him a view of the cranial portion of the tumour, which was found to be indenting the undersurface of the frontal lobe. On pushing brain and dura gently back, he could see the whole extent of the cranial portion of the tumour. It at first appeared to be fixed to the supraorbital margin, but it was not so.

It was removed mainly by hammer and chisel, but the orbital roof portion was got away by means of cutting forceps, piecemeal. Complete recovery ensued; very little scarring remained, vision was normal, and there was neither diplopia nor fundus change. The tumour must have been growing from the frontal sinus. There was no evidence that the operator had broken into that sinus; he was looking out for such a contingency, from the point of view of possible sepsis, and also impediment to respiratory movements. On the day following the operation, however, and for a day or two succeeding, there was some escape of blood from the nostril. But the frontal sinus was evidently aseptic, as there was no further happening. The operator was congratulated by several speakers.

Tumor of Orbit.

Mr. J. F. Cunningham showed a case of cartilaginous tumor of the roof of the orbit. Colonel Armour advised operation.

Angioma of Retina.

Mr. Elmore Brewerton exhibited an instance of angioma of retina. The pathology was somewhat difficult, but he considered it a cavernous angioma. He gave his reasons for believing that the distension of veins was mechanical, and that the disease was in the lower oval swelling in the periphery. Such cases were practically never seen in old age. He regarded it as a congenital faulty development of the capillaries in that part of the retina, that these capillaries dilated into cavernous spaces, and there ensued an oval limited area of angioma. The prognosis in the case he did not regard as favourable; the vein would probably, sooner or later, begin to leak, indeed there was already slight exudation. The patient would probably have an intraocular hemorrhage, which might clear up, but a second one would result in the loss of his sight.

Mr. A. W. Ormond thought these cases were interesting on account of the other eye. A patient of his told him he had an eye removed at five years of age for a suspected growth. The condition was somewhat similar to what Coats described as massive exudation of the retina.

Hereditary Optic Atrophy.

Dr. James Taylor read a short communication on "Changes in the Sella Turcica in Association with Leber's Atrophy." The changes were very evident by the epidiascopic demonstration, especially in the posterior and anterior glenoid fossa. The paper seemed to confirm the thesis of Mr. Herbert Fisher, that these ocular and intracranial alterations were associated with definite sexual changes.

The President considered the paper an advance. Ogilvie's enquiry into the high infantile death-rate in families afflicted with Leber's atrophy seemed to point the way for further light.

Mr. J. Herbert Fisher reminded members that his contention was that Leber's optic atrophy was probably due to implication of visual pathways by the pituitary body, which at the time was undergoing excessive

changes, either in development or decline. He had since had a remarkable case in which all the symtoms came on in a woman aged 37 soon after her menopause at that age, and there also the sella turcica was definitely altered in comparison with the normal. If his thesis was correct, he did not know why separate, sporadic cases should not occur. Ogilvie's investigation seemed to make likely that the high infantile mortality might be due to syphilitic taint.

Fundus Drawings.

Captain W. Wallace gave an interesting exhibition, by the epidiascope, of numerous drawings he had made of fundus changes resulting from war injuries. He offered his whole collection, which he had been working at for many years, to the profession, and Professor Herbert Parsons expressed the hope that they might be made the nucleus of an ophthalmologic atlas as a record of ophthalmologic work done during the war.

Sympathetic Ophthalmitis.

Mr. Foster Moore read a paper on a case of sympathetic ophthalmitis, with fundus changes. He said that sympathetic ophthalmitis was of rare occurrence during the war, therefore every case was worth recording. In this case, the fundus changes developed during the progress of the disease, and were visible throughout. The man had a penetrating wound of the right eye, and presented himself with a prolapse of the iris and ciliary body. The prolapse was removed on the seventh day after the wound and the eye was taken out a fortnight later.

The first sign of anything amiss with the left eye occurred 20 days after enucleation of the right, in the form of slight mistiness. Two days later, when Mr. Foster Moore saw him, there was slight tenderness on palpating the eye, and a fine deep haze was present in the lower part of the cornea. The fundus was normal, but there was some distention of veins. The appearance of the central part, around the stump of the optic nerve, caused the author to suspect that uvea had been left behind; but it was found that the eye had been cleanly removed and there was no uveal pigment left.

Six weeks after the original wound there was a fresh crop of keratitis punctata spots. The blood count was normal. Skiagraphy did not reveal any foreign body; Wassermann was negative. There was a marked increase in the keratitis punctata, but later that disappeared, though it subsequently reappeared. Five doses of neosalvarsan were given.

The writer exhibited drawings showing the degree of keratitis punctata, which were made by Mr. Frank Juler. He did not think the mercury had any influence on the disease. That also was the view of a special committee of the Ophthalmological Society appointed to consider the subject of sympathetic ophthalmitis, for they said they did not consider that mercurial inunctions had any decidedly bad effect on sympathetic ophthalmitis.

H. Dickinson.

OPHTHALMOLOGICAL SECTION
BALTIMORE CITY MEDICAL SOCIETY

Meeting at Presbyterian Hospital
February 19, 1919

Operation for Closed Pupil.

Dr. Herbert Harlan exhibited a woman in whose case he used the De Wecker's scissors for operating upon a closed pupil following cataract extraction, with very good visual results. He stated that it was his experience that this method gave much better and more permanent results than any other which he had used.

Buphthalmos.

Dr. Harlan also exhibited a child with buphthalmos for which he performed an iridectomy. So far as he could see there had been no change in the eye since operation. He also reported a case of buphthalmos following interstitial keratitis, for which he had performed a cilio-optical neurotomy.

The eye appeared somewhat smaller although it had only been two weeks since the operation.

Operation for Strabismus.

Dr. Catlin presented a case of convergent strabismus which had been operated upon by the Briggs' tucking method. The results were very satisfactory.

In discussion Dr. Harlan stated that he was very well pleased with this method of operation.

Neuro-retinitis.

Dr. Fleming showed a case of neuro-retinitis, with star shaped exudate at the macula, in a young man of twenty-seven with visual acuity of 20/50; in whom all tests had been negative.

In discussion it was suggested that a provocative Wasserman be done, and a spinal puncture.

Pemphigus of Conjunctiva.

Dr. C. A. Clapp exhibited a case of extensive conjunctival degeneration with involvement of the cornea in a man of seventy, who gave a rather indefinite history of trouble with his eyes since fourteen years of age, with operation on the lids for entropion at that time. The right eye showed numerous bands across each fornix, with superficial vascularization of cornea and vision of 5/200. The left eye presented the same condition about the fornices, but with a dense white opacity of leather-like appearance over the cornea, which was exceedingly dry. In spite of numerous diagnoses of trachoma, he held that the case was one of pemphigus in the late stages, which did not exhibit the blisters that occurred in the early stages. Dr. Harlan confirmed his diagnosis.

Detachment of Retina.

Dr. Janney exhibited a case of bilateral detachment, in a young man of twenty, with negative Wassermann and other findings. In discussion it was suggested that he also have a provocative Wassermann.

No further business, meeting adjourned.

C. A. Clapp, *Secretary.*

SECTION ON OPHTHALMOLOGY COLLEGE OF PHYSICIANS OF PHILADELPHIA

December 19, 1918

Dr. S. Lewis Ziegler,

Acting Chairman.

Metastatic Uveitis.

Dr. Charles R. Heed detailed clinical notes of a case of bilateral metastatic infection of the uveal tract in a boy during the course of cerebrospinal meningitis, due to the meningococcus. The patient, aged ten years, complained of poor vision four days after the onset of the disease. First examination of eyes showed a marked yellowish exudate covering the pupillary space, with turbidity of aqueous, discolored irides and pupils fixed. Tension plus one, and vision reduced to light perception in each eye. The inflammation progressed for three days and then began to subside. On the eighth day the aqueous was clear, exudate less dense and vision, right eye, hand movements, left eye, counting fingers at eight inches. Improvement continued, and two months after first examination there was a very moderate circumcorneal injection, a few tags of posterior synechia and several dots on Descemet's membrane. The fundus reflex clearing showed a few vitreous opacities, the optic discs showing evidence of a previous neuritis, and far forward there were areas of a low-grade choroiditis. The unusual restoration of vision in this case is credited to four intraspinal injections of meningococcic serum.

Dr. William M. Sweet stated that he saw the case at the height of the inflammation. At that time the exudation in the right eye covered the pupillary area and a portion of the iris to the nasal side. In the left eye the exudation was less in amount. The light perception was poor in both eyes, and in the right eye was uncertain except in the upper outer quadrant. Dr. Sweet regarded the improvement in vision as remarkable in view of the amount of exudative inflammation.

A Case Showing a V-Shaped Iridotomy.

Dr. S. Lewis Ziegler exhibited a patient with membranous occlusion of the pupil in right eye, following postoperative infection of a complicated cataract. There was a history of iritis twenty-five years previous, with exclusion of pupil. When first seen the operated eye was still congested, but this was controlled by positive galvanism. On November 22, 1918, a V-shaped iridotomy was performed with the Ziegler knife-needle entering the corneoscleral junction above and making two long converging incisions in the iridocapsular membrane from below upward. The pupil opened up freely in the form of a triangle with base downward. Vision = 2/200. Refraction gave 20/70 with S + 11.D = C + 1.D Ax. 110° and J-12 with S + 3.D added. A faint opalescent reflex over the vitreous surface, exposed in the artificial pupil, suggests the possibility that an adventitious hyaloid membrane may be forming. If the suspicion proves correct this membrane will be incised in the hope of improving the vision.

On November 30, 1918, the cataract in the left eye was extracted, first inserting a modification of Kalt's suture in order to quickly close the globe and protect it against infection. Double-threaded needles were inserted, one in the sclera above the proposed incision and the other in the cornea just below it. A Graefe knife was passed between the threads, a large section of adherent iris was excised and the lens quickly removed. The lens was semitransparent but the nucleus was hard. The cortex did not escape freely, owing to its gluey character. The corneal suture was drawn taut and tied, thus making a firm self-supporting mattress suture. The field of operation was treated as an open wound with free irrigation and applications of ice pads. Altho some flakes of muco-pus were several times noted, there was no infection or other untoward symptom. There is considerable swollen cortical, but this is absorbing slowly. A secondary capsulotomy will, of course, be required later.

Injury from Rat Poison.

Dr. McCluney Radcliffe reported a case of loss of eye, the result of an explosion of a tin of "Common Sense" rat poison.

While the patient was prying off the lid of the can it exploded with sufficient force to break her spectacle lens and cut a jagged wound in the cornea, the iris prolapsing.

The incarcerated iris was excised, and the wound closed.

The lens was cataractous, and finally panophthalmitis developed, necessitating enucleation of the eyeball. On section of the ball a wedged-shaped piece of glass, 8 mm. long, 3 mm. wide and 2 mm. thick, was found in the vitreous just back of the lens. The vitreous was filled with pus.

Conjunctival Scars from Inherited Lues.

Dr. J. Milton Griscom exhibited a girl, aged seven years, who had unusually well-marked facial and dental signs of congenital syphilis. She also had prominent areas of scar tissue on the conjunctival surface of both upper and lower lids. These resembled the scars seen after trachoma, but there were no signs of previous corneal involvement or evidence of distortion of the lids. Both parents were free from any evidence of trachoma, and it was considered that the conjunctival scars were the result of a prenatal syphilitic infection, with the probable formation of conjunctival gummata previous to birth.

Division of Head Surgery. — (Office of the Surgeon-General, with Special Reference to Ophthalmology.)

Colonel Walter R. Parker presented by invitation a very interesting and instructive paper which will be published in full in this Journal.

Discussion. Lieutenant-Colonel de Schweinitz, supplementing Colonel Parker's address on the activities of the Division of Surgery of the Head, and referring entirely to the Section

of Ophthalmology of the Medical Corps of the United States Army, spoke of the endeavor which had been constantly present to keep the ophthalmic personnel at a high standard of efficiency. To this end, in addition to the camp instruction to which Colonel Parker had referred, and the various addresses which had been made during camp inspections, the School of Ophthalmology in connection with United States General Hospital No. 14 at Fort Oglethorpe, was founded during the summer. It had been in contemplation for a long time, but the actual organization did not take place until July of the present year. This school had afforded the opportunity, because of the qualifying examinations which were necessary for entrance, as well as the qualifying examinations which were required at the end of a four weeks' intensive training course to remain in the ophthalmic work of the army, of greatly improving the selection of those men needed to fill the various ophthalmic positions. The abundant material used in teaching, as well as the carefully planned operative course and the cooperative work with the other departments of the hospital, for example, in neurology, urology, general medicine, oral and plastic surgery, had made it possible to develop a work which was the equivalent of any high-grade postgraduate ophthalmic course in the country and in point of fact, in many respects was superior to it. After the school had been fully organized it was placed in charge of Major Meyer Wiener, and he and his associates had done admirable work.

Colonel de Schweinitz briefly referred to the opportunities that had been his own to study the types and needs of war ophthalmic work in France during the fall and winter of 1917 and 1918, and the observations made there had been incorporated as much as possible in the work on this side of the water. He did not attempt to describe the very complete organization of the ophthalmic work of the A. E. F., in charge of Lieutenant-Colonel Greenwood, ably assisted by Lieutenant-Colonels Black and Derby. Doubtless these officers would on their return make full description of their work. Colonel de Schweinitz paid a high tribute to the skill and effectiveness with which Colonel Parker had conducted his duties as Chief of the Division of Surgery of the Head in the Surgeon General's Office.

Fatty Degeneration of the Cornea.

Dr. Burton Chance exhibited a woman, aged sixty-eight years. The disease was first noticed about a year ago, altho no cause could be assigned for it by the patient. The area was elliptical in outline and occupied the lower hemisphere of the left cornea. The horizontal diameter was about 6 mm., the vertical 4 mm. The plaque was yellow and greatly resembled the appearance of highly polished old ivory. It lay beneath the epithelium and was quite distinctly demarcated from the healthy cornea. In the relation between it and the sound tissue it might have been likened to the lunule of the finger nail, but so distinctly did it appear that at a distance, so solid was it, it might have been mistaken for a dislocated calcareous lens in the anterior chamber. The epithelium at the center had become eroded by a stiff eyelash in the lower lid. This irritation had excited injection and had caused a fine leash of vessels to extend over the surface from the lower limbus. Elsewhere there were no blood vessels. There were no other signs of disease. The area had given rise to no symptoms other than blurred sight as the mass extended quite above the pupillary border.

It is likely that the disease arose from long continued irritation of the surface of the cornea by distorted eyelashes.

J. Milton Griscom, M. D.,
Clerk.

ABSTRACTS

Raeder, G. Instrument for Measuring Depth of Anterior Chamber. (Thalamometer.) Norsk Magazine for Laegevidenskaben. 1918. p. 862.

Raeder in working to measure the depth of the anterior chamber with a binocular corneal microscope ascribes his varying results in the same patient at different examinations to the unconscious movement of the patient in the interval between the focusing of the instrument on the anterior surface of the cornea and the later focusing on the edge of the iris.

To overcome this difficulty he has constructed a single tube instrument by which the focusing on the two points (cornea and iris) is done *simultaneously*. This is accomplished by leading the rays from one-half of the field of the microscope thru a series of adjustable prisms allowing the images of the cornea and the iris to fall in the same perpendicular plane and thus to be seen by the observer's eye at the same time. The depth of the chamber is read off directly on a scale attached to one of the prisms. Accuracy up to 0.1 mm. is claimed. The surface of the cornea is brought into view by dusting it with finely powdered calomel or xeroform.

Since the anterior surface of the lens is difficult to observe, the edge of the pupil is used as the point of fixation.

Corrections are made for variations due to differences in the size of the pupil.

D. L. Tilderquist.

Frenkel, H. The Traumatic Syndrome of the Anterior Segment of the Eye. Ann. d' Ocul., Feb., 1918, v. 155, p. 78.) Frenkel describes 66 cases, of which 58 were war injuries, consisting of 7 shot, 40 shell, 3 grenade, 2 torpedo, 1 gun cap. The civil accidents were 2 splinters of wood, 1 piece of rock, 2 horse's foot, 2 fists, 2 falls and 2 whips. The following symptoms were found: Periocular lesion—7 supero-external orbital margin, 20 supero-internal, 9 inferior, 1 zygomatic arch, 10 root of the nose, 1 ala of the nose, 1 ridge of the nose, 13 upper lid, 11 lower lid, 4 forehead, 5 cheek and face.

The *cornea* is always intact in this syndrome. In most recent cases there is hyphemia, the anterior chamber is deeper than normal, 31, some in toto, some in part; diminished in 22, some in toto, some in part.

The iris showed: (a) Rents; iridodialysis 23, perforation 29, rarefaction of tissue 8, rupture of the pupillary margin 1, dilatation of the pupillary margin 1, partial atrophy of the pupillary margin 1, notching of the pupillary margin 1, detachment of the iris 1, atrophy of the iris 1.

(b) Semicircular folding of the iris 8, 1 double.

(c) Trembling 23.

Pupil—Changes were: (a) Form—mydriasis 52, racket shaped 9, oval 16, round 5, deformed 14, festooned margin 5.

(b) Dislocation—21 cases in various directions.

(c) Reaction—Feeble 13, very feeble 8, abolished to light 22, to accommodation 21, partial below only 1, temporal side only, 1.

Dislocations of the Lens—(a) With rotation above and anteriorly 1.

(b) Anteroposteriorly, 12.

(c) Frontally, 25.

(d) Combination, 9.

(e) Not indicated, 19.

Cataract — (a) Stationary — anterior subcapsular, 35; posterior subcapsular, 5; perinuclear, 9; equatorial, 2.

(b) Progressive—Total, 2; intumescent, 2; operated, 3; spontaneously absorbed, 1.

Complications — Traumatic retinochoroiditis, 12; detachment of the retina, 5; vitreous opacities, 6; atrophy of nerve, 4; posterior, 5; increase of tension, 1, following anterior dislocation of the lens; strabismus, 5; facial paralysis, 1.

Diminution of visual acuity was an almost constant factor, independent of lesions of the posterior part of the eye. It was probably in great part due to dislocation of the lens. In 37 cases it was below 1/20, in the remainder it ranged from 1/10 to 8/10. Refractive errors in the injured eye were M. 1, H. 6, H. Ast. 1. The accommodation showed nothing distinctive.

Altho some of the lesions found are due to indirect violence, those of the iris and lens are most probably due to direct action on the region of the zonula of Zinn, the force being applied obliquely. After the blood is absorbed from the anterior chamber, the state of the eye remains stationary, except for the development of an occasional cataract. Sight is always poor, even after cataract operation. Treatment consists in measures to promote the absorption, of the hyphemia, dionin, subconjunctival injections, cataract operation, and treatment of the periocular injury.

C. L.

A. Frias Oñate. Cocain in Ophthalmic Practice. Revista de Medicina y Cirugía de la Habana, Nov. 10, 1918.

The author mentions several cases of serious collapse from the use of 10 per cent solution of cocain. Frias thinks that the 3 and 4% solutions are not sufficient to produce anesthesia. The author believes that fresh solutions should be used every time, and he states that the collapse is probably not due to an emotion on the part of the patient, but to the fact that old solutions are used. Frias states that he uses in his ophthalmic operations a solution 20 per cent in strength, which (no doubt) gives him a perfect anesthesia. Nervous patients, old people and children, should put the eye surgeon on guard.

F. M. Fernandez.

Rasquin, E. Charts for the Determination of Professional Visual Acuity and Vision for Military Service. (Ann. d' Ocul., Mar., 1918. v. 155, p. 117) defines the *minimum visible angle* as the smallest angle under which the luminous object is visible, and the *minimum sparable angle* that which permits two neighboring points to be distinguished. The former is smaller than the latter and depends on the intensity of the illumination, while the latter depends on the elements of the retina and is equal to one minute. Based upon this, numerous well known test charts have been constructed. But for the purpose of estimating the loss of vision for work, for the estimation of damages and for the granting of pension, a chart is needed which shall fill two conditions: (1) It shall be composed of characters recognizable by all and constructed according to ophthalmologic principles; and (2) It shall furnish a uniform gradation appropriate to the requirements. The broken rings of Landolt adopted by the VI Int. Congress, at Naples, is theoretically correct and adapted to most cases, but in the case of unintelligent patients localization is sometimes very difficult, especially the oblique directions, e. g., 45%, etc.

For various reasons the author rejects other forms of test cards in use, and describes the ones he advocates. Starting with the assumption that visual acuity diminishes in arithmetic ratio while the visual angle increases in geometric, he has constructed three scales or charts, one composed of letters and figures (Snellen); one of E, but with all three bars of equal length, turned up, down, right or left; and one squares with a break in the upper or lower, right or left side. He prefers the first two in estimating the loss of capacity for work. The chart consists of 12 lines, the first 11 increasing by geometrical progression at a ratio of 1.2231, representing vision from 0.1 to 0.75, the 12th line is so constructed that the image is partly extra macular and indicates a vision of 0.05. The chart should be read at a distance of 5 M.

Below is given a scale for estimating, in general, the visual acuity, according to the chart. To determine the partial incapacity of the patient, count the number of lines between the upper and lower limits of acuity for his work which gives the denominator of a frac-

tion the numerator of which is the difference between that number and the position of the line which the patient can read below the upper limit for his work. For example, the patient has an occupation which requires an acuity of between 1/2 and 1/20. The scale shows 9 lines between the upper and lower limits. The professional acuity for this occupation is therefore divided into ninths. If he reads the third line which follows the upper limit he possesses $\frac{9-3}{6}$ =6/9 profession-acuity.

Linear Dimension		Distance at which line should be read	Physiologic visual acuity	Professional Visual Acuity			
				Professional visual requirements			"War"
Letters	Parts			High	Medium	Low	
7.27 mm.	1.46 mm.	5.00 M.	1	1	1	1	1
9.72 mm.	1.94 mm.	6.67 M.	0.75	1	1	1	1
11.87 mm.	2.37 mm.	8.16 M.	0.61	9/10	1	1	11/12
14.52 mm.	2.90 mm.	9.98 M.	0.5	8/10	9/10	1	10/12
17.76 mm.	3.55 mm.	12.21 M.	0.41	7/10	8/10	9/10	9/12
21.72 mm.	4.34 mm.	14.93 M.	0.33	6/10	7/10	8/10	8/12
26.56 mm.	5.31 mm.	18.26 M.	0.27	5/10	6/10	7/10	7/12
32.49 mm.	6.50 mm.	22.34 M.	0.22	4/10	5/10	6/10	6/12

C. L.

Dimmer, War Injuries and Sympathetic Ophthalmia. Klin. Monatsb. f. Augenheilk., v. 57, p. 257.

Sympathetic ophthalmia has certainly occurred only very rarely during the present war. In the clinical material of the Vienna University Eye Clinic, not one case had been noted up to July, 1916.

v. Grosz had not seen a single case of sympathetic ophthalmia during the first year of the war. The number of injuries included in his report is very large. He saw 406 injuries from rifle bullets, of which 145 cases became blind in one eye and 40 in both eyes. In 168 cases of shrapnel injuries, unilateral blindness resulted 121 times and bilateral blindness 15 times. One hundred and eighteen injuries were due to explosion; in 69 of these, one eye alone became blind and in 7 both eyes. Further, there were 31 contusions, among which were 12 scleral ruptures and 8 stab wounds, with unilateral blindness in 5 cases. Two hundred and fifty-four eyes were enucleated: 158 of these were bullet injuries, 59 shrapnel injuries, 31 explosion injuries, 4 scleral ruptures, and 4 stab wounds.

Salzman in Graz has not observed any sympathetic ophthalmia among those injured in the war. Uhthoff treated 252 direct injuries of the eyeball, among wounded soldiers with total blindness in 48 percent of these eyes. Uhthoff saw no case of sympathetic ophthalmia. R. Oleynik in a report on eye injuries, makes the direct statement that no case of sympathetic ophthalmia had been observed.

Positive cases of sympathetic ophthalmia following injuries in the present war are reported by Birch-Hirschfeld, M. Sachs and Krusius. Birch-Hirschfeld reports an injury by a splinter of a bomb, 18 days before the case came to the hospital. The eye showed a mild iridocyclitis; few precipitates on Descemet's membrane; cataract; globe slightly tender to the touch; and movements visible directly in front of the eye. Enucleation was resorted to at once. Two days later, the fellow eye

showed typical signs of sympathetic disease. M. Sachs made an oral report of a case. The eye was enucleated late, and shortly after the enucleation, typical sympathetic disease appeared in the fellow eye. The statements of Krusius are too general to permit of any definite conclusions.

v. Grosz, Jessop and de Lapersonne refer to the great number of cases of sympathetic ophthalmia during the Franco-Prussian war, 1870-71. Grosz remarks, that this disease claimed many victims during the Franco-Prussian war as compared to the present war.

Dimmer noted the striking disproportion between the large number of cases of sympathetic ophthalmia during the Franco-Prussian war of 1870-71 and the very few cases observed in the present war; but could not convince himself, that this could be attributed to the better treatment of the eye injuries today. He questioned whether all the cases published in the war of 1870-71 were really sympathetic ophthalmia, and what was the character of the process in those cases which can be regarded with certainty as sympathetic ophthalmia.

In the Military Report of the German Army in the war with France, 1870-71 Dimmer found recorded 99 cases of sympathetic ophthalmia among the German wounded. After a careful study of the histories of these cases, he comes to the conclusion: that among the 99 recorded, not a single case of undoubted sympathetic ophthalmia can be found; and that the statements in the literature concerning the large number of sympathetic ophthalmias in the German army in the war of 1870 and the resulting great number of cases of blindness, should be rectified, since the reports at hand show, that altho sympathetic irritations were observed repeatedly, not one case of undoubted sympathetic ophthalmia could be ascertained.

Returning to the question of sympathetic ophthalmia in the present war, he repeats that this disease certainly occurs very rarely, and that this is by no means inconsistent with conditions in the war of 1870-71, as shown by a study of the case histories. He urges that the question of sympathetic ophthalmia among the injured in the present war be studied more minutely with especial reference to the following points: The question of the sanitary measures, and the question of pathogenesis of sympathetic ophthalmia. Some of the results of the investigations will yield information in both directions. If, for instance, we determine the period of time between the injury and the enucleation, we are informed on the one hand, whether the injured were properly treated, and on the other hand, it will be of scientific interest, should it be shown that sympathetic ophthalmia was observed, altho rarely, notwithstanding the fact that the injured eyes in a large number of instances were removed in due time.

Reviewing the war injuries of his clinic, with reference to the time that had elapsed between the injury and the enucleation, he found the following: The total number of enucleations was 142, including cases enucleated elsewhere which came to the clinic for examination. Of these, 60 were gunshot injuries, 16 bombshell, 36 shrapnel, 3 stone splinter, 8 hoof kick, 5 stone cast 3 bayonet stab, 1 cartridge, 1 explosion, 1 glass, 1 tree branch, 1 blow. In 11 of these cases the date of the injury could not be obtained, so that the interval between the injury and the enucleation was ascertained in 131. Of these 22 were enucleated within the first 2 weeks after injury; 46 cases, 2 to 4 weeks; 24 cases, 4 to 8 weeks; 20 cases, 6 to 8 weeks, and 19 cases still later than 8 weeks. This shows that in a very large number of cases (83.2 per cent), enucleation was resorted to later than absolute protection against sympathetic ophthalmia is to be expected.

Dimmer gives the following possible reasons for the rare occurrence of sympathetic ophthalmia among war injuries: 1. Enucleation is resorted to within a shorter space of time after the injury. 2. The healthy condition of the wounded soldier may make him less susceptible to the disease.

Schirmer has shown that sympathetic ophthalmia generally appears within the first year after the injury, and usually after the fourth week; most frequently between the sixth and the twelfth week after the injury. If it could be shown in a very large number of war injuries that sympathetic ophthalmia was observed almost without exception where the injured eye was removed relatively late, i. e., after the sixth week; and if the number of sympathetic ophthalmias is about the same as that which we ordinarily find after injuries or eye diseases which are prone to cause sympathetic ophthalmia, then we would have to conclude: that the marked reduction in the number of sympathetic ophthalmias in war injuries is due to timely enucleation, a fact that would deserve the widest publication.

If the rare occurrence of sympathetic ophthalmia in war injuries, is not due to the early enucleation, but to internal causes, then an explanation of this fact would have to be looked for. There may be a certain predisposition on the part of some individuals; poorly nourished patients and lymphatic children are prone to the disease. Changes in the blood were reported by Ormond and later verified by others.

If internal causes are to be accepted as a reason for the rare occurrence of sympathetic ophthalmia in the war injuries, the physical fitness of the soldier deserves consideration; and whether or not some general condition, overlooked at the time of medical examination, or which developed later in the course of the war, could be responsible in those cases which have acquired sympathetic ophthalmia.

Antonio Alonso. Langrange's and Elliot's Operations in Glaucoma. (III National Medical Congress of Mexico. Puebla, 1918.)

The author gives full credit to Lagrange for the priority of the idea of deliberately forming a subconjunctival fistula for the relief of glaucoma, Holth's method with the punch hole and Elliot's trephine being only varieties of technic. He quotes at large the investigations made on animals' eyes by Rochon-Duvigneaud and Bonnefon, from which it has been proved that the loss of substance in the sclera and also in the cornea, have a great tendency to cicatrization, according to the ordinary laws of physiology.

In glaucomatous eyes, however, the conditions which are necessary for obtaining a good subconjunctival filtration and a permanent reduction of the intraocular tension are not yet known. Lagrange states that only the section in a longitudinal way of one of the borders of the scleral wound, can give constant and permanent results.

Elliot's operation is a good method, easily mastered, which must be applied especially in cases of malignant or hemorrhagic glaucoma, in which the section of the cornea, even a small one, is liable to great dangers for the eye, such as loss of vitreous, lens luxation and profuse or expulsive intraocular hemorrhage. Trephining is also indicated in chronic glaucomas and in some of the subacute and secondary types; but in acute glaucoma the best operation will always be the old von Graefe iridectomy.

According to Alonso, the conjunctival flap, as made by Elliot, is difficult to dissect without perforation. He has used with great advantage a flap made from the sclero-corneal margin backward, similar to that used by Dupuy-Dutemps and Van Lint for cataract extraction. Two lateral sutures are made in order to cover the wound. He recommends also instead of the Elliot's trephine the von Hippel automatic instrument, which is easily applied and without danger.

The paper ends with the report of 15 cases of trephining with good results, in several forms of glaucoma.

ALLIES IN OPHTHALMOLOGY.

The idea of a world congress of ophthalmology, referred to last month, should not be lost sight of; but meanwhile, individual ophthalmologists who can visit the other side of the Atlantic, should try to attend the national ophthalmic associations of the countries they visit.

In Great Britain the Ophthamological Society of the United Kingdom will meet in London, May 1st to 3d. The special subject for discussion will be "Visual Requirements for Aviators;" and Col. Wilmer of Washington is expected to take a leading part. The Bowman Lecture will be given by Morax of Paris, and there will be visits to the blind and myopia schools and to the Central London Ophthalmic Hospital.

When the Oxford Congress meets July 10th to 12th, it is to be hoped that the congestion of ocean travel will be less extreme than it still is; and the opportunity for spending vacation weeks in the rural regions and resorts of Great Britain will again be open to American visitors. It is worth while this year to make a special effort to meet British ophthalmologists on their own ground.

Paris is still almost a closed city to casual visitors, but within the next few months, we may hope that conditions will be returning to near the normal; and in Paris and other continental centers, the ophthalmmologist will meet a new respect for all things American, and a cordiality of welcome rarely known before. The desire to get in closer touch with us is expressed in many ways in the letters received by the editors of the Journal.

A collaborator writes to one of the editors: "When shall we have the pleasure to see you in Paris? Clemenceau said the other day: 'We met as friends and will part as brothers.' You really cannot postpone a voyage to Europe." This is not merely personal, it is the invitation of French ophthalmologists toward their American confreres.

A still more detailed and emphatic invitation comes to another of our edi-

tors from London; it is an appeal that should be heard and heeded:

"I am writing to ask you if there is any chance of your being able to attend the Oxford Congress of Ophthalmology, this year. We have kept it in being right through the war, though it meant a sore struggle to do so. Now we want to open out again, and to recall its former triumphs and to excel them. You know our founder kept before him the ideals that this congress should be free from formality, that all should be welcome there, and that the youngest might speak and be sympathetically listened to by all alike. Above all our watchword is Internationalism. We want to see the peoples who stood by us in the fight for the world's freedom, gathered with us in profitable discussion and in friendly social intercourse. I want your help personally, because I admire your work so much, and the same is true of us all, as a council or as a congress. Will you come and will you do something; show us something new; give us a lecture, or a demonstration; do anything! If you really cannot come, will you try to interest some of your Chicago members to both come, and to do something. They will be sincerely welcomed. I hope you will both come and get others to do so.

"If there is one ideal dearer to me than any other, it is to cement the bonds that unite the Anglo-Saxon peoples, and all who speak the tongue of freedom. To me the English-speaking peoples should be one in sympathy, as they have shown themselves one in all that is best, in courage, in care for the weak, and in sacrifice of all they count dearest for the call of honour and right. Oxford is one of the opportunities of meeting and getting to know each other. Will you put your persuasive pen and your yet more persuasive mind to work to help on our meeting?

"The best of everything to you and to all my many friends under the Stars and Stripes."

The force of such an appeal to both the heart and intelligence must be felt by every American ophthalmologist.

E. J.

TRAINING FOR OPHTHALMIC PRACTICE.

Interest in this subject should not be confined to a few teachers of ophthalmology, and the relatively small proportion of medical graduates who are seeking such training as preparation for special practice. It is important to the whole medical profession and the whole community. The imperfect development of courses in ophthalmology, and their neglect by those who should avail themselves of them, impair the service that they should be fitted to render to physicians and their patients. There are especially important reasons why every one practicing ophthalmology should give active attention and thought to this matter.

When Germany decided that war should be used to achieve world domination, there were in attendance at her medical schools and clinics 298 students from America, of whom a relatively large proportion were studying ophthalmology. For five years this stream of students has been wholly interrupted. For many more years it will be impossible for German universities to give even such instruction as they have given in the past.

Anarchy and arson, war debts, the loss of old teachers, and the interrupted development of new ones, combine to bring about this change; while on the other side the feeling of disgust and contempt for the professors who prostituted their position in the world of science to serve imperial autocracy and militarism, are strongly operative.

Ophthalmology must be taught elsewhere than in the clinics of Germany, and it can best be done in the medical institutions of America. In bringing about a better appreciation of the needs for such teaching, and what such teaching should be, American ophthalmologists must do some active work.

The first thing to do in this direction is to get a general conception of what training for ophthalmic practice ought to be, and how impossible it has been to get the right kind of training in the past. In the last few months we have had numerous expressions with

regard to it. In this number are included two papers with regard to it, and three letters bearing upon it will be found in this issue under the head of correspondence.

The first letter is published without giving its author's name because he is out of the country, and because its significance cannot be appreciated without an explanation of how carefully this well known ophthalmologist had tried to prepare himself for his work. He was a college graduate before he studied medicine. He took a three years' course in medicine when the mass of students were graduating after two five months' courses of lectures. Then he served full terms as interne in one of the best known general hospitals of America, and in one of the largest eye hospitals. After that he studied many months in the great eye clinics of Europe.

Returning to this country, he quickly became the leading ophthalmologist in one of our large Eastern cities. His well used opportunities for special study were greater than those of most of us, yet they were so far below what we have a right to expect in the way of systematic training that he says: "Our generation picked up in the most casual manner what little we got to know."

The other letters were selected from among those which have come to the editor in the last few months, as showing independent views on this subject. One of them estimates the deficiencies of opportunities for ophthalmic training now offered in this country, even when selected with wise discrimination, and used with intelligence and earnestness. The other expresses a hope that has arisen among American ophthalmologists, that something will soon be done to establish schools for preparation for ophthalmic practice. A further account of the army school referred to in the third letter will be published in an early number of this Journal.

When we have gotten a conception of what training for ophthalmic practice ought to be, in this age of educational institutions, laboratories and hospitals, we ought to exert our influence as individuals and thru our organizations to see that the right sort of training is offered and that the inertia of tradition is overcome to utilize it.

In at least a dozen strong universities that have medical departments there should be established courses, chiefly laboratory, on physical and physiologic optics, and on the anatomy, histology, physiology, and pathology of the eye, and on the anatomy and physiology of the visual tracts and centers, and the principles of ocular diagnosis. These are not the only things that are needed in the training for ophthalmic practice; but they are the things that have been most neglected, and can be best taught with a good university equipment.

Every clinical school for teaching ophthalmology should call attention in its announcements to the importance of such courses as preliminary to clinical study. When the mass of its students come with such preparation for its clinical work, it will be able to give far more efficient and satisfactory courses of clinical instruction. The stronger, more ambitious postgraduate medical schools, supplied with fair laboratories, might well undertake to give such fundamental courses in ophthalmology within their own walls.

Every prospective student of ophthalmology as a branch for special practice, will seek the advice of some ophthalmologist as to the best course of study to pursue. Every ophthalmologist, conscious of the difficulties with which he has had to contend, should be ready to advise the student as to how and where he can spend his time, effort and money, to the best advantage to himself and the public he expects to serve. Every graduate in medicine can exert some influence with his Alma Mater or the university of his city or state, to bring about a practical recognition of the need of reasonable training for ophthalmic practice. All influence possible will be needed, to hasten such a desirable advance in the

method of making ophthalmologists, at this time when the students of the world are seeking new centers of medical teaching.

E. J.

DONDERS AND GRAEFE.

All we can learn of these great men must be of interest to ophthalmologists; and we are particularly fortunate in having the letters (published p. 277) which passed between them preserved and so adequately translated into English. Seldom have letters of such deep autobiographic interest been published.

It is interesting to note that Donders, Jaeger and Graefe met when they were all studying ophthalmology in London; and how the enthusiasm of the youngest, Graefe, flamed up in friendship for his older, more self-contained and balanced comrade. His enthusiasm and his appreciation of achievements, which, if greater, were less spectacular than his own, and attracting far less attention at the time, marks the true greatness of Graefe.

In these letters, which reveal the deep desires and hunger for comradeship on the part of the ophthalmologist, who, more than any other one, made Germany the great center for ophthalmic training, we can catch a glimpse of those springs of human action that usually remain deeply hidden in the individual life.

It may be regretted that the corresponding letters of Donders have been destroyed with something of that disregard for all that is of other than German origin that has been creeping like a palsy on the scientific life of Germany since 1870 when Graefe died. But we may well doubt if Donders' letters were so self-revealing, altho they might have contained much of scientific interest. It is unfortunate that of American ophthalmologists who went abroad to study in the last generation, more did not go to Utrecht rather than Berlin. We must suspect that the trend of Graefe's genius, toward striking operative achievements, better caught and held the interest of the "practical" American students. It is interesting to find that he had so just an appreciation of the value of operative achievements as compared with the more purely scientific far-reaching labors of his colleagues.

E. J.

BOOK NOTICES.

COMUNICACIONES DEL HOSPITAL OFTALMOLOGICO. Reports from the Ophthalmic Hospital of Buenos Aires. Vo. I, No. 1, December, 1918. Royal 8vo., pp. 160.

We have before taken occasion to mark the development and activity of a center of ophthalmology in Buenos Aires. These are again forced on our attention by these hospital reports. Making their initial appearance, they are found to bear well a comparison with the first parts of the Reports of the Royal London Ophthalmic Hospital, London, or Donders' Hospital Reports, from Utrecht. They are not surpassed in general scientific value by any Ophthalmic Hospital Reports that have appeared in the United States.

The scope of the work may be judged by the subjects of the eight reports by as many authors, which comprise the bulk of the work. These are: Sanguineous Infiltration of the Cornea, Acute Dacryoadenitis, Tuberculous Periphlebitis of the Retina, Ophthalmoplegia, Nodding and Rotary Spasm, Megalocornea, Pontine Cerebellar Tumor, and Arteriovenous Aneurism of the Internal Carotid. In addition there is a Review Department of 20 pages containing abstracts of 13 articles relating to ophthalmology taken, not from European sources, but from the medical publications of Argentina.

These reports are well illustrated. The article of 70 pages on Ophthalmoplegia contains 56 illustrations in the text, mostly reproductions of photographs of cases. The paper on Retinal Periphlebitis has a colored plate representing the condition. Every article except the first one has one or more illustrations; and most of them are excellent. We note the absence of an

index, but this may come in a later part.

The appearance of this new series of hospital reports is a subject for congratulation, not only to its sponsors and contributors, but also to the ophthalmologists of the world. If one wishes to make the acquaintance of the Spanish language, and the literature of ophthalmology published in it, we know of no collection of papers of higher scientific value and literary excellence thru which he may enter upon such a study.

E. J.

CORRESPONDENCE.

Training in Ophthalmology

To the Editor:

I cannot resist the temptation to write you a line to say how much I have been impressed with your thoughtful article on Defects of Education for Ophthalmic Practice in the July number of the JOURNAL, which I received recently.

As you say, "Those of us who are engaged in ophthalmic practice are more or less conscious of our deficiencies," and as one looks back it is easy to see how great a proportion of these deficiencies could have been obviated by a little systematic training. Our generation picked up in the most casual manner what little we got to know. I spent a year in the Wills Eye Hospital, but it took me more than a month learning to see the fundus, an accomplishment which I have many times enabled men to acquire in half an hour. The Wills Hospital staff were all capable men, and I found them kind, but they were too busy to give special instruction, *and it was not their business.*

Probably the remedies you suggest are about the best that we can hope for for some time; but I think that in time special schools of ophthalmology will be established in connection with universities in a few (perhaps the fewer the better), of the large cities. These schools will give a thorough course, beginning with mathematics, optics, ocular anatomy, etc. The diploma given by these institutions will be so desirable that they will attract more and more men. Their examinations will be severe as the instruction will be thorough. Such schools in the nature of things cannot be self-supporting, but the example of Carnegie and Rockefeller will doubtless be followed by others, so that endowments may be expected. * * *

To the Editor:

After reading, again and again, your paper in the AMERICAN JOURNAL OF OPHTHALMOLOGY, (v. i, p. 482), I write you, telling how I appreciate your opinions and expression on this subject.

In the fall of 1915, I gave up my general practice, and took up my studies of the eye as well as the ear, nose, and throat. I wanted the best school, so I thought my selection was a wise one when I went to New York and entered the New York Post Graduate School. I was surprised at my capacity to apply myself. I worked harder than I did in my undergraduate school, for over eight months. Feeling that I was not getting as good instruction as I wished for, I worked during my spare time at the Eye and Ear Infirmary. I spared neither money, nor effort. But when I left New York I felt that I had failed to attain what I sought and desired.

So I wondered and thought, and tried again and again to examine myself. While I realize that my deficiencies are many, I can't help but conclude that the teachings, or rather the methods of teaching in all the Post Graduate schools, especially in the special, are very sadly deficient. I feel too modest and humble to undertake a crusade on the subject of post-graduate schools. Altho I approached several postgraduates on the subject and they agreed with me, yet I do not feel of enough force to be able to carry any reform thru. Reading your paper revived my spirits, and I feel that I must be right, as others are thinking the same.

I am writing to express my appreciation and approval of your opinion on

the subject, and expressing my hopes that you will continue vigorous action toward a reform. I hope that the American Medical Association will some day take this matter up; and institute some regulations in the matter of postgraduate schools and thereby protect the many physicians who honestly and earnestly are seeking to improve themselves for the good of the profession and humanity.

As for myself; I shall not get discouraged. I shall plug along, read, observe, and work diligently until some day I hope to attain the position of the efficient; and hope that if I ever rise enough to be heard, I shall enter into the effort to cause a reform, with all my might and with all my influence.

Very truly yours,
M. H. Heldman.

Great Falls, Montana.

To the Editor:

I have read with intense interest Colonel de Schweinitz's account of the Army School of Ophthalmology. Such a school located in one (or more) of the large cities (Baltimore, Philadelphia, Chicago, Denver), is certainly needed.

A majority of the four thousand American oculists would enjoy and profit by such courses at times. At the same time, if properly conducted, with well paid teachers, the school would furnish a standard of efficiency for those wishing to study and practice ophthalmology as a specialty. The difficulties were great (and have not been lessened, I believe), in getting instruction of the kind detailed in Colonel de Schweinitz's article in your issue, December, 1918. Well trained teachers, if well paid, might easily be attracted to such service.

I earnestly wish you could propose such a permanent School of Ophthalmology.

Yours truly,
Edward F. Parker.

Charleston, S. C.

NEWS ITEMS

Personals and items of interest should be sent to Dr. Melville Black, 424 Metropolitan Building, Denver, Colorado. They should be sent in by the 25th of the month. The following gentlemen have consented to supply the news from their respective sections: Dr. Edmond E. Blaauw, Buffalo; Dr. H. Alexander Brown, San Francisco; Dr. V. A. Chapman, Milwaukee; Dr. Robert Fagin, Memphis; Dr. M. Feingold, New Orleans; Dr. Wm. F. Hardy, St. Louis; Dr. Geo. F. Keiper, LaFayette, Indiana; Dr. Geo. H. Kress, Los Angeles; Dr. W. H. Lowell, Boston; Dr. Pacheco Luna, Guatemala City, Central America; Dr. Wm. R. Murray, Minneapolis; Dr. G. Oram Ring, Philadelphia; Dr. Chas. P. Small, Chicago; Dr. John E. Virden, New York City; Dr. John O. McReynolds, Dallas, Texas; Dr. Edward F. Parker, Charleston, S. C. Volunteers are needed in other localities.

DEATHS.

Dr. John B. Hazel, Hoopeston, Illinois, aged 69, died at his home, January 20th, from heart disease.

Dr. John G. Hersh, East Greenville, Pa., aged 66, died at his home, February 2nd, from bronchial pneumonia.

PERSONALS.

Dr. J. W. Jervey has just announced the opening of a modern Eye, Ear and Throat Hospital in Greenville, South Carolina.

Dr. Luther Peter of Philadelphia has been elected Professor of Ophthalmology in the Post Graduate School of the University of Pennsylvania.

Dr. Ervin Wright, of Huntington, Indiana, has gone to Rolla, Missouri, to continue eye, ear, nose and throat practice.

Dr. William Campbell Posey, after twenty-five years of valued service as Surgeon to Wills Eye Hospital, Philadelphia, has resigned from the institution and has been succeeded by Dr. T. E. Conrad.

MILITARY NOTES.

Dr. W. E. Kershner, Major, M. R. C., has resumed practice at Bath, Maine.

Dr. J. J. Smith has returned to practice in San Francisco after service in the United States Army.

Capt. A. B. Middleton has been released from the service, and has resumed his practice at Pontiac, Illinois.

Dr. H. M. Krebs of Huntington, Indiana, has been promoted to Lieut.-Col. and has resumed his practice in Huntington.

Capt. W. A. Sedwick of Denver has been transferred from Camp Grant to U. S. General Hospital, Biltmore, North Carolina.

Capt. Alfred Cowan of Philadelphia, Instructor in Ophthalmology at Camp Oglethorpe, after a year of service has resumed private practice at 2018 Chestnut street.

B. F. Baerr, Jr., of Philadelphia, who went abroad as Ophthalmic Surgeon with Base Hospital Unit of the University of Pennsylvania, has been relieved from service and has resumed private practice at 2037 Chestnut street.

Lieut. Wm. M. Bane, who was with Base Hospital No. 29, A. E. F., London, has returned to Denver to resume his association with his father, Dr. Wm. C. Bane.

Capt. Wm. C. Finnoff has returned to his home in Denver to resume practice. He will be associated with Dr. Edward Jackson. Dr. Finnoff had a most valuable experience with Base Hospital Number 29 as ophthalmologist.

Major George W. Jean, M. C., U. S. Army, returned from France early in February. While overseas he was chief consultant on the eye for the five Base Hospitals located at Rimaucourt, Haute-Marne. After two months in California he will resume his practice in New York City.

Major Burton Chance, who was assigned to the U. S. Hospital No. 11, Cape May, New Jersey, May, 1918, in charge of the Division of Ophthalmology, was released from service December 6, 1918, and has been appointed Lieutenant-Colonel, Medical Corps, U. S. Reserve.

Captain Charles M. Stiles, of Philadelphia, began his Army service by a brief period of training at Camps Greenleaf and McClellan, and on October 16, 1917, was placed in charge of the Division of Ophthalmology at Camp Wadsworth, South Carolina, where he remained for fourteen months. Captain Stiles has recently been released from service, and has resumed his practice.

Colonel Gilbert E. Seaman, after returning from overseas duty, recently gave Doctors Howard Ford Hansell, and G. Oram Ring of Philadelphia the pleasure of a brief visit. Colonel Seaman served in the Philippines from 1898 to 1900. He entered the U. S. Service in connection with the recent war as Lieutenant Colonel, and was made Chief Surgeon of the 32nd Division of the Sixth Army Corps. He will shortly resume his Eye, Ear, Nose and Throat practice in Milwaukee.

COMING MEETINGS.

Section on Ophthalmology, American Medical Association, Atlantic City, New Jersey, June 9-13.

American Ophthalmological Society, Atlantic City, New Jersey, June 13-17.

Pacific Coast Oto-Ophthalmic Society, San Francisco, California, August 4-6.

American Academy of Ophthalmology and Oto-Laryngology, September 2-3.

Ophthalmological Society of the United Kingdom, London, May 1-3.

Société Française d' Ophtalmologie, Paris, May 5th.

Oxford Ophthalmological Congress, Oxford, England, July 10-12.

MISCELLANEOUS.

A Seventh Trachoma Hospital established by the U. S. Government has been opened in La Moure, North Dakota, under the charge of Dr. Clarence E. Downs.

Soldiers blinded in war, who are receiving vocational training at United States Hospital Number 7, Evergreen Junior, have received a gift of nearly $3,000 from the Baltimore committee of the Woman's Homeopathic Base Hospital Unit.

A mass meeting in honor of Sir Arthur Pearson, Mr. Douglas McMurtrie, Lieut.-Col. James Bordley, was held January 28th at Orchestra Hall, Chicago, under the auspices of the New York Red Cross Institute for Crippled and Disabled Men and the Service League for the Handicapped, of Chicago.

The National Committee for the Prevention of Blindness is asking contributions from public spirited persons toward the sum of $20,000 to further their great work in the prevention of blindness. Checks should be made payable to Mr. George Blagden, 130 East Twenty-second street, New York.

The Chicago Lighthouse is the name of a new institution conducted by the Improvement Association for Blind People, to teach the blind useful occupations so that they may become self-supporting. It is located at 3323 West Twenty-second street, Chicago. Miss Phyllis Bayley is the director, Mrs. Harry J. Ilett, president, and Sir Arthur Pearson, honorary president. The Board of Advisers is composed of eight of Chicago's prominent men.

Four new books from the pen of Sir. J. W. Barrett, of the University of Melbourne, are announced by H. K. Lewis and Co., of London. Now ready, "The Australian Army Medical Corps in Egypt," and "The Twin Ideals, An Educated Commonwealth," (reviewed in this Journal, v. 1, p. 871); and in press "A Vision of the Possible, What the R. A. M. C. Might Become," and "The War Work of the Y. M. C. A. in Egypt."

Harry Gulf, of Gallatin County, Wis., has returned to his home with a war record that makes one feel that the war should be resumed. In the Argonne, the last battle of the war he was wounded and taken prisoner by the Germans. The Hun monsters who captured him, wounded and completely at their mercy, actually punched out his eyes, forever destroying his sight. At this time the young man's left foot was torn off by a shot, and numerous other wounds inflicted.

According to the *Shelbyville Republican* people in that part of Indiana have been learning by costly experience the ways of the traveling oculist, or the swindler who calls himself an oculist. Two such adventurers by pretending to find a growth on the eye and doing a fake operation to remove it, were able to effect the actual removal of two hundred and seventy-five dollars from one patient, and one hundred and sixty from another.

The first number of the "Comunicaciones del Hospital Oftalmologico" was issued in December, 1918, from Buenos Aires, A. R. Its object is to collect and publish the papers of the staff of the Hospital Oftalmologico, which has fourteen oculists and five physicians for consultation in neurology, medicine, etc., and two internes. This hospital examined and treated 15,000 new patients last year. There are eight papers and a review of the Argentine literature in this issue.

The American Board of Ophthalmic Examination will hold its next examinations at the Wills Eye Hospital, Philadelphia, June 6 and 7, 1919. This is the fifth examination to be conducted by the Board, which is composed of representatives of the American Ophthalmological Society, the Section of Ophthalmology of the A. M. A., and the Academy of Ophthalmology and Oto-Laryngology. The many war activities have interfered with the work of the board for the past year, but from now on it is expected that great activity will prevail. Complete information can be had by writing Dr. Wm. H. Wilder, 122 South Michigan avenue, Chicago.

The Council of British Ophthalmologists appointed a committee consisting of eminent ophthalmologists and physicists to determine standards of illumination for Snellen's test types for distant vision. The committee reports: 1. There is a rapid rise in acuity as the illumination is increased from zero up to about two "foot candles." 2. Above three foot candles there is scarcely any rise in acuity. It is possible to lay down precise and simple rules. Two ordinary 20 Watt tungsten lamps, with straight filaments are fixed vertically fifteen inches in front of the plane of the test card, one on each side at a horizontal distance of twelve inches from the vertical normal to and bisecting the card. One lamp is placed higher than the other, one being opposite the junction of the upper and middle thirds of the card, the other opposite the junction of the middle and lower thirds. Opaque, non-reflecting screens are fitted so as to prevent direct light from reaching the candidate's eye.

The days of the blind beggar are numbered. The familiar figure with his tin cup, his dark glasses and his sign, "Please help the blind," was largely the creature of circumstance. There was nothing else for him to do. Today a blind man finds it possible to be reeducated and to continue a useful member of society. Sir Arthur Pearson, a millionaire publisher, of London, totally blind, is in this country, telling us of the wonders that have been accomplished for blinded soldiers and sailors at St. Dunstan's Hospital, London. It was the wonderful progress made by the blinded soldiers of England that prompted that nation to make such enormous strides in the reeducation of its blind, and it is to be hoped that the remarkable capacity of our own blinded heroes, just returned from the battlefield, will direct the thought of our nation to our own civilian blind. It is a matter for state action and is a field that the wealthy can work in. What could be more satisfying in one's declining years than to superintend the erection of an institution for the reeducation of the blind and then endow it with funds to perpetuate its existence, that it might act as a living monument of usefulness to the donor's name forever?

As stated in the circular memoranda for Editors of Medical Publications issued by the Surgeon General's Office on March 27th and May 22d, 1918, it is required by paragraph 423, Manual of the Medical Department, that all medical manuscripts by medical officers, U. S. Army, intended for publication shall be first submitted to the Surgeon General's Office, Washington, D. C., for approval. This regulation, which has been very courteously complied with, to date, is still in force as far as medical officers on active duty are concerned. In the case of medical officers recently retired from active duty, it is requested, as a courtesy to the Surgeon General and in aid of assembling material for the Medical History of the War, that all medical manuscripts based upon military or official records or upon military experience during the War, be submitted as heretofore, to the Secretary, Board of Publications, Surgeon General's Office, Washington, D. C., for record and approval, and that such MSS. be accompanied by a carbon copy. Upon approval, the original copy will be forwarded to the journal designated, for publication, and the carbon will be filed in the records of the Medical History of the War.

For the Surgeon General:

(Signed) C. R. Darnall,
Colonel, Medical Corps, U. S. A.,
Executive Officer.

OPHTHALMIC LITERATURE

These lists contain the titles of all papers bearing on Ophthalmology received within the preceeding month. These titles are all in English, some of them modified to indicate more clearly their subjects. These subjects are grouped under appropriate heads, the succession of groups being the same from month to month. In the group the papers are arranged alphabetically usually by the name of the author in heavy-face type. After the subject of the paper (Ill.) indicates the number of illustrations. (Pl.) the number of plates, and (Col. pl.) colored plates illustrating the article. (Abst.) shows that it is an abstract of the original article. (Bibl.) tells that the paper is accompanied by an important bibliography. (Dis.) means that a discussion of the subject is published with it. Under Repeated Titles are indicated additional publication of papers already noticed. To secure the earliest possible notice writers may send copies of their papers, or reprints, to 318 Majestic Bldg., Denver, Colorado.

CONCERNING CONCUSSION AND CONTUSION INJURIES OF THE EYE IN WARFARE.

LT. COL. GEORGE E. DE SCHWEINITZ, M. C., U. S. ARMY.

PHILADELPHIA, PA.

This paper reviews a subject of which our knowledge has been greatly extended by the experiences of the present war. It was read before the College of Physicians of Philadelphia, February 5th, 1919. Authority to publish granted, Board of Publication, S. G. O.

It is plainly evident that in the insistent work, nervous energy and scientific curiosity of life man tries to be "ever reaping something new." Therefore it is that the question is constantly asked by laymen as well as by physicians: "What are the new discoveries, new methods of procedure and new therapeutic measures which the science and art of medicine and surgery have acquired and put into practice during this war, now happily in abeyance?"

They, the investigations of the laboratory and the work of preventive medicine, contribute a long catalog in which ophthalmology has obtained a not inconspicuous place. We could with profit discuss with one another the improvements and advances which have been made in blepharoplasty and keratoplasty, in prosthesis, in dermic and epidermic and cartilage implantations and props, in the extraction of metallic and nonmetallic intraocular foreign bodies, in the prevention of sympathetic ophthalmia and of ocular sepsis and in the improvement of "first aid" technic.

Interesting as such a discussion might prove to be, with your permission, this communication shall concern itself only with some of the results of ocular concussion and contusion—injuries in warfare, and makes mention of some of the pathogenic problems which they present, of certain of the differences which are evident as compared with the results of such injuries in civilian life, and of one or two new clinical pictures.

The experience on which the observations are based was obtained in three "eye centers" of the British Medical Service in France, and two General Hospitals to which wounded were evacuated in England, one French "eye center," and in all of the "eye centers" except one which have been established in this country since the wounded have arrived in large numbers. In the last-named "centers" naturally none of the lesions was of recent date, most of them having occurred weeks, and many of them several months prior to their examination.

Already a large literature has accumulated on this subject and is scattered thru various journals published in France, England, Italy and Germany, and at least two important Atlases have been produced, namely "Atlas d'Ophtalmoscopie de Guerre,"[2] by Lagrange, and "Atlas der Kriegesaugenheilkunde," by v. Szily.[2] Colonel W. T. Lister[3] of the English R. M. C. has made notable contributions, for example, "Pathological Aspects of War Injuries of the Eye." No attempt is made to analyze the scattered literature, but to the text of the two atlases named and to the recorded observations of Colonel Lister constant reference shall be made.

Causes.—In general terms the fundus lesions now under discussion are caused *directly* by a blow, or sudden forceful pressure, on the eyeball, behind, from the side, or tangentially; or *indirectly,* by the transmission of concussion or shock.

In the first instance the lesions are classified as *lesions by contact;* in the second instance they are *lesions by concussion.*

The contact lesions are caused, for example, by a missile which grazes the globe but does not rupture it, or by a fragment or portion of a fractured orbital wall or floor or roof, thrust harshly against the eyeball.

The concussion lesions are caused: (a) by concussion at a distance, for instance, violent displacement of air by the explosion of a shell (Lagrange); (b) by transmission of concussion or shock thru the bony facial structures; and moreover, not only thru those near to the eye, to wit, the malar bones and orbital margins, but thru the superior maxilla (especially if the missile passes thru the antrum), and the inferior maxilla, some authors, notably Lagrange, believing that the vibratory concussion proceeds to the orbital contents thru the pterygo-maxillary fossa and fissure; and (c) by slight blows on the anterior part of the eye, the concussion being transmitted thru the transparent media to the posterior pole (Lagrange).

The lesions as usually described may be summarized thus: (1) Lesions by concussion, (2) lesions by impact, and (3) combined lesions, i. e., both by concussion and impact with the lesions in front of or adjacent to the spot of contact, and also immediately opposite to the site of impact; or, in another sense, as lesions which are not associated with and lesions which are associated with fracture or perforation of the orbit (passage of a missile thru it). This rule in the distribution of lesions makes ophthalmoscopic examination of great value in determining the course of the missile.

In the first case, as before noted, the concussion is transmitted from a distance (par ébranlement de l'air), or thru the bony facial structures, or thru the cornea and transparent media, the orbital walls, floor, roof or cavity not being directly injured.

In the second instance, there is traumatism of the frontal region and radiating fracture of the orbital vault, or passage of a missile thru the orbit behind with injury of the optic nerve, but not of the bulb, or passage of a missile thru the orbit tangentially to the eye, grazing it but not rupturing the globe. Should the lesions of the inner membranes result from a concussion at a distance, their development has been attributed to the commotion of the air-column shaking the ocular wall in the same manner as it shakes the door in a room. Should the concussion waves reach the eye in a line of transmission thru the bony facial structure, the effect has been likened to the lifting up and shaking of a ship by a ground swell, and the entire adipose envelope is concussioned, resulting in ruptures of the inner ocular coats (Lagrange).

In this connection it may be interesting to quote from an editorial review of Bonnet's[4] recent contribution to the study of the effect of shell explosions on the human organism, published in the Journal of the American Medical Association, February 8, 1919. Bonnet explains the nervous and pulmonary lesions which follow shell explosions by assuming "that the aerial wave-compression acts primarily on the superficial capillaries and bloodvessels, as well as those of the abdominal cavity; in short, those not protected by nature from pressure. There is thus formed a blood column which is driven like a battering ram into incompressible cavities, like the thorax and the cerebro-spinal cavity. As a result the smaller vessels in these cavities may rupture, causing varying amounts of injury. The eye and the ear are especially liable to suffer, the former by its position exposed to pressure, and the latter by its physiologic adaptability to receiving pressure."

Symptomatology.—Of external manifestations there may be none at all, or often at most edema of the lid, diffuse redness, or a patch of congestion or ecchymosis. In other words, absence

of outward signs is not necessarily an indication of lack of intraocular lesions, and moreover, of extensive ones: Therefore routine ophthalmoscopic examination of the eyes of wounded soldiers, whenever possible, has revealed many times elaborate retinochoroidal and vitreous changes. Thus, I examined an English soldier within forty-eight hours after he was hit. He had severe arm and leg wounds and probably tangential orbital injuries. Externally his eyes were practically clear, and yet in both of them there was much vitreous hemorrhage and extensive concussion changes in each fundus.

Naturally, the character and degree of the visual depreciation depends upon the extent, situation and age of the lesions. An interesting and evidently an important fact, dwelt upon by Colonel Lister, is that in severe concussion resulting in commotio retinae, presently to be referred to, vision may be completely lost for several days, followed by a return, and as a matter of course in the serious types there is often permanent reduction of visual acuteness.

The visual field changes evidently depend upon the location of the lesion and its depth and character. But to the correlation of lesions of the retina with defects in the field of vision much study has been given, especially by Colonel Lister. As a matter of interest his observations may be quoted in summary thus: "Lesions above or below the horizontal plane were found to cause defect in the field out of all proportion to the local disturbance, a "distribution defect" being found in addition to the local defect due to the lesions. This is due to the fact that not only was the spot struck damaged, but also nerve fibers in the immediate vicinity which were passing on to a more peripheral portion of the retina. This distribution defect is fan-shaped, the expanded portion being peripheral and the nearer the lesion is to the disk, the greater is the blind sector, and vice versa. When the lesion occurs in the horizontal plane there is no "distribution defect" found, as the fibers supplying the retina in the horizontal line arch around from the disk to their destination, and therefore these lesions can only involve the nerve fibers at their terminations."[5] Scotomas of various shapes may interpret the macular and paramacular alterations.

Marked reduction of intraocular tension is common in many of these cases. The statement that lowered eyeball tension is an important sign of perforating scleral wounds, and especially of diagnostic import when, for example, a small penetrating wound of the sclera is covered with tumid, and it may be swollen, conjunctiva, must not be taken unreservedly in view of the many observations in this war. Indeed, as the late Mr. Nettleship said in the discussion of a case of prolonged hypotony after contusion recorded by E. Treacher Collins,[6] the practical interest in the report consisted in the demonstration that reduced tension of the eye does not necessarily mean wound or rupture of the globe.

Collins suggests that diminished tension of short duration is due to increased rate of excretion of intraocular fluid thru expanded normal channels of exit, or to arrest of secretion from paresis of intraocular nerves; and that diminished tension of long duration is due to the formation of new channels of exit, or to rupture of the pectinate ligament, or detachment of the pars ciliaris retinae. Magitot[7] ascribes the variations in ocular tension to the action of the trauma upon the intraocular vasomotor nervous system.

The ophthalmoscopic pictures of the variously transmitted *concussion* and *impact* effects necessarily vary according to the stage of the process at which they are examined, but in general terms may be divided into *primary* and *secondary* changes.

The commotio retinae of Berlin, so often noted in civilian practice, after blows on the eye, for example, the impact of a tennis ball or a flying cork, may be summarized as follows: Hyperemia of the globe marking the position of contact of the missile; clear media; and gray opalescence of the retina, especially in the macular region,

but also around the papilla, which may be somewhat hyperemic. If the retina under the point of contact is visible, this also may exhibit the white infiltration. In addition, several pale, yellowish spots, and, occasionally, small hemorrhages may be present. The vessels are unchanged, or, in some instances, are contracted (arteries) or distended (veins) and pass *over* the gray area. A central scotoma may exist. The gray infiltration forms quickly and is also absorbed with rapidity, usually having subsided at the end of two or three days, altho the visual defect may last for longer periods.

The commotio retinae produced by such war injuries as have been referred to differs somewhat from the Berlin type in the presence of more numerous hemorrhages, the yellow tint of the so-called retinal haze, its longer duration and more circumscribed character.

An interesting but evanescent picture has been observed and particularly described by Colonel Lister in the later stages of commotio retinae, after disappearance of the haze; namely, peculiar striae in the vicinity of the macula, almost certainly due to the wrinkling of the swollen retinal layers.

Lister calls attention to the "grossly concussioned fundus," where in the early stages there are widespread clouds of hemorrhage, many gleaming and glistening white particles, which gradually fade, become converted into fibrous tissue, and represent originally patches of coagulation necrosis from rupture of retinal and choroidal vessels.

Lacerations of the choroid and retina, or of their vessels, or of both, followed by hemorrhage beneath the retina and into the vitreous, are common. They depend in part upon stretching of these membranes by the vibrations in the vitreous. They are frequently placed at the posterior pole of the eye and near the papilla. These situations are peculiarly liable, according to some observers, probably because the sclera, thicker around the entrance of the optic nerve than elsewhere, does not readily stretch. Its resistance in this regard causes the effect of the force to be more potent on the tissue just in front of it. Accumulation of transuded serum and of hemorrhage between the choroid and retina, and between the choroid and sclera may cause detachment of the retina and of the choroid.

The lesions just recited are *primary*, whether due to concussion, contusion, or impact. They naturally lead to the *secondary* lesions, the most important being atrophic chorio-retinitis (spots of atrophy, exposed scleral areas and pigment distribution, heaping and fringing), and proliferating chorioretinitis. If the extravasations on the retina and choroid are absorbed, many of the well-known appearances of pigmented atrophic chorioretinitis are evolved, tho frequently its elaboration is most extensive, especially in fan-shaped, pigmented granular areas. Blood may escape, and often does, into the vitreous and be absorbed, leaving all manner of opacities in its place.

This chorioretinitis proliferans is essentially a cicatricial process; there is organization of hemorrhage, but this is of less importance than its irritating effect on the connective tissue of the retinochoroidal layers, inciting the active proliferation and the formation of tracts, areas and masses of fibrous tissue. The whole process and picture differ materially from the so-called proliferating retinitis of recurring hemorrhages in the vitreous and retina, especially in young subjects, often noted in civilian practice. In the type which follows war injuries the retina and choroid have been ruptured, and the cicatricial process leads rather to a pinning down of the retina by opaque, plastic-looking material than to its detachment, so frequent in the ordinary variety, in which the proliferation arises from extravasated blood, and the numerous membranes, following the vessels, often partly translucent, protrude freely into the vitreous. As you know, Lagrange has constructed in tabular form the chief differential diagnostic points, as briefly indicated.

In the concussion-contusion injuries of the eye in civil life the so-called "holes" at the macula are comparatively common, while, according to

Colonel Lister, these holes in military practice are rare. This, however, has not been my own experience. Within the last six weeks, among about twenty-five cases of the types we are considering, I have seen four typical holes in the macula, the surrounding areas splotched with pigmented retinochoroidal changes.

Some authors, for instance Lagrange, have occasionally noted defective vision, central scotoma and no evidence of ophthalmoscopic change in the macula. This I have not observed, but I have seen a fundus free from pathologic signs, except a delicate stippling of the macula and a minute Y-shaped choroidal rupture; one case recently studied with Major Suker followed a blow delivered on the orbital ridge of the affected eye. It required careful focussing to detect it.

On the other hand, in place of the usual impact and concussion lesions, there may be extensive disorganization of the interior of the eye (without rupture): liquefaction and infiltration of the vitreous, widespread masses of yellowish-white exudation and large detachment of the retina. In a remarkable case recently investigated the soldier had been wounded in the head, probably by a missile passing thru both orbits, and the X-ray showed a large fragment located near the Gasserian ganglion. In the right eye the vitreous was thickly infiltrated, the fundus difficult to see, but covered with yellowish exudation, and the retina detached below. In the left eye, over the disk and partly hiding it, there was a mass of fibrous material; otherwise no changes, and vision 20/xxx. While under observation this left disk within two weeks developed a typical choking of 7 D., depending on late formation of pus in the track of the missile.

Notable are the cases of injury of the optic nerve in the canal, by a missile passing thru the orbit posteriorly, which sometimes cuts across the nerve, or the nerve is injured by a radiating fracture of the orbit. Mostly the result is an irremediable atrophy of the nerve and blindness. Hematoma of the sheath of the optic nerve has often been found, resulting in atrophy. Peripapillary hemorrhage in these cases is rare; but a peripapillary brown ring, due to hemic pigment, is a diagnostic symptom in the later stages. Atrophy of the nerve is the usual result.

Avulsion of the optic nerve, which is jerked from its socket, is not infrequent. After the hemorrhage absorbs a traumatic excavation is visible — a kind of "coloboma or surgical conus," as Lagrange calls it. This may be filled up later with proliferated connective tissue. The retinal vessels above and below the excavation may be comparatively normal. This has been often noted, and recently well figured and commented upon by Edward Jackson.[8] In the report of Parsons' case of division of the optic nerve by a stab-wound, quoted by Jackson, Parsons[9] states the vessels refill thru direct and indirect cilioretinal anastomosis, the blood being derived from intact anterior and posterior ciliary arteries. In a case studied within the last two weeks, the missile, i. e., a fragment of a high-explosive shell, entered at the lower and outer angle of the left orbit, shattered the eye, passed behind the root of the nose and probably thru the frontal sinus and certainly thru the posterior part of the orbit and came out beneath the skin of the right temple. The right eye had extensive retinochoroidal changes and the optic nerve had evidently been partly or completely jerked from its entrance. This entrance was covered in with a proliferated fibrous mass, but the vessels were fairly well intact.

Frequency and Distinctiveness of the Lesions.—In general terms, contusion and concussion injuries of the eye in this war have been frequent, and those which have followed oblique wounds of the facial bony structures have represented about 6 to 8 per cent of the whole number. Thus Rollet and Velter, among 3,915 wounded, noted 343 examples of lesions of the deep coats of the eye without disorganization of the eyeball, a percentage of 8.76.[9] It is of interest to note that a concussion sent thru the maxillofacial area of one side and causing ipsolateral ocular le-

sions is probably prevented from producing like lesions in the opposite eye because the nasal accessory sinuses prevent the concussion or shock from passing to that globe.

There seems very little doubt that lesions of the inner eye by concussion from a distance, by concussion transmitted thru the bony facial structures and following blows on the point of the eye, by preference are located in the macula and paramacular area; that impact lesions are equatorial and always adjacent to the site of contact; that a contact lesion may spread toward the center; that posterior pole and equatorial contact lesions may approach and join each other; and that missiles traversing posterior to the bulbus and radiating fractures of the orbital vault are responsible for most of the direct optic nerve injuries. Whether it is safe to say that impact lesions are always, or almost always, retinochoroidal and concussion lesions choroidal, as Lagrange contends, it would seem is not settled.

Unquestionably the difference between concussion changes of the fundus encountered in civil and military practice depends, as Lister points out, in greatest measure upon the fact that in ordinary circumstances the blow is delivered by a comparatively slow-moving object, while in warfare the missile passing thru the orbit moves rapidly.

As special types of concussion and contusion injuries as observed in warfare in comparison with those seen in civil practice, we may note the character of the commotio retinae, the elaboration of the severely concussioned lesions and in particular the distinctive character of the traumatic proliferating chorioretinitis. Finally, it should be noted that all observers comment on the analogy between the mechanism of these concussion injuries of the eye and those of the brain.

Treatment.—In the hope of stimulating extravasated blood and exudation, the usual alterative, diaphoretic and lymphogog remedies (the iodides, sweats and dionin), may be tried, as may electricity, especially for those eyes with much vitreous change. Thyroid extract is also employed. I am frankly skeptical whether remedial agents have much influence, and more than skeptical as to the value of subconjunctival injections. In a certain number of apparently severely concussioned eyes after long periods of time there has occurred notable improvement in vision. Transitory astigmatism after direct concussion has often been noted

[The paper was illustrated and the various types of concussion and impact injuries portrayed by means of a series of diagrams taken from Lagrange's and v. Szily's Atlases, and some water colors by the late Miss Margaretta Washington of concussion injuries in civil practice. Drawings which are to be made of the fundus lesions studied in the various American Eye centers were not at the time available.]

ACTIVITIES OF THE DIVISION OF SURGERY OF THE HEAD, OFFICE OF THE SURGEON-GENERAL.

COLONEL WALTER R. PARKER, M. C., U. S. ARMY.

DETROIT, MICHIGAN.

This resumé of the organization and work of the Division of Surgery of the Head in the Office of the Surgeon-General of the United States Army was read before the Section of Ophthalmology of the College of Physicians of Philadelphia, December 19, 1918. Authority to publish granted, Board of Publication, S. G. O.

In May 1917 the General Medical Board of the Council of National Defense at the suggestion of Dr. James Bordley Jr., appointed a subcommittee in ophthalmology and in August of the same year authorized a subcommittee in otolaryngology. The personnel of these committees was made up in part at least of members of the committees previously appointed by the special national societies and special sections of the American Medical Association, at the request of the chairman of the General Medical Board of the Council of National Defense.

The personnel of each committee was as follows: Ophthalmology—Dr. James Bordley, Jr., chairman, Dr. George E. de Schweinitz, Dr. Allen Greenwood, Dr. Nelson M. Black, Dr. Walter R. Parker, Dr. W. H. Wilmer; Oto-laryngology—Dr. Charles W. Richardson, chairman, Dr. Harris P. Mosher, Dr. Burt R. Shurly. The work of the subcommittee of Ophthalmology began with the preparation of a catalog of the ophthalmologists of the country which included nearly nine thousand names. To each name a questionnaire was mailed on June 13, 1917 and as a result over fourteen hundred signified their willingness to serve.

The subcommittee of Oto-laryngology later made a similar list of the oto-laryngologists of the country and questionnaires were sent to fifty-six hundred oto-laryngologists.

Later the two committees were consolidated and a representative from the army and navy added, together with a representative of brain surgery and oral and plastic surgery. The personnel of the committee as finally constituted was as follows: Dr. Wm. H. Wilmer, chairman, Dr. Nelson M. Black, secretary, Dr. James Bordley, Jr., Dr. George E. de Schweinitz, Dr. Allen Greenwood, Dr. Walter R. Parker, Dr. Charles W. Richardson, Dr. Charles Bagley, Jr., Dr. Harris P. Mosher, Capt. V. P. Blair, Major T. C. Lyster, M. C., U. S. Army, Surgeon G. E. Trible, M C., U. S. Navy. The new members of the joint committee, viz: Dr. Chas. Bagley, Jr., representative of brain surgery and Capt. V. P. Blair representative of plastic and oral surgery, proceeded by means of questionnaires signed by their respective committees, to classify the surgeons in the country who were qualified as brain or plastic and oral surgeons.

The Surgeon General of the Army had been kept in close touch with all phases of the development of the work of these committees and had determined upon the establishment of a division of surgery of the head in his office to be under the charge of Major T. C. Lyster. This plan was authorized July 9, 1917, and quarters in the Surgeon General's office were assigned and opened with the following personnel: Major T. C. Lyster, chief of the division, Major Nelson M. Black, in charge of Ophthalmology, Major Harris P. Mosher, in charge of Oto-laryngology, Capt. Chas Bagley, Jr., in charge of brain surgery, Capt. V. P. Blair in charge of Plastic and Oral surgery. The personnel thus formed in the surgeon general's office worked with the remaining members of the committee, who were on volunteer service in Washington, to secure personnel and develop the organization.

August 15, 1917, the Surgeon General authorized the organization of a special head hospital of one thousand

beds to be operated in connection with the hospitals of the A. E. F. Special committees were appointed to carry out these plans.

With the increased activities of the Division of Surgery of the Head in the Surgeon General's Office it became necessary to increase the personnel of the organization, until finally by the last of September every member of the original committee of the Council was in uniform and all but three on duty in the Surgeon General's Office. Major James Bordley, Jr., was assigned to the Division of Reconstruction, Major Wm. H. Wilmer to aviation, Major Burt R. Shurly was director of the Red Cross Hospital No. 36 which went to France early and is still functioning overseas. Three additional officers were added to the staff in the Surgeon General's Office making the personnel of the Division as follows: Major T. C. Lyster, in charge of the division; Major Nelson M. Black, in charge of Ophthalmology; Major Harris P. Mosher, in charge of Oto-laryngology; Capt. Chas. Bagley, Jr., in charge of Brain Surgery; Capt. V. P. Blair, in charge of Plastic and Oral Surgery; Capt. Robert H. Ivy, assistant in Plastic and Oral Surgery; Major M. G. Seelig, Assistant in Brain Surgery and in charge of publications; Capt. H. H. Kerr, Assistant in Brain Surgery; Major Walter R. Parker, assigned to the Section of Ophthalmology in charge of the construction of Special Head Hospital No. 115; Major Allen Greenwood, assigned to the Section of Ophthalmology with special duties in reference to the personnel of Special Hospital No. 115, Major George E. de Schweinitz, assigned to the Section of Ophthalmology in charge of equipment of Special Hospital No. 115 and especial publications. Later Major Kerr was assigned overseas and Capt. (now Major), Grover C. Pemberty, was assigned Assistant in Brain Surgery.

Major, now Brigadier General, Lyster, in company with Major, (now Lt. Colonel) de Schweinitz and Major, (now Lt. Colonel) Mosher, made a tour of inspection abroad. During the absence of this committee Major, (now Colonel), Walter R. Parker was placed temporarily in charge of the Division of Surgery of the Head and later was made Officer in Charge. Later Major Blair went overseas and Captain, (now Major), Ivy was left in charge of Plastic and Oral Surgery. Still later Major Ivy went overseas and Major G. V. I. Brown was assigned to his duties.

In the Section of Ophthalmology Major Greenwood went overseas in charge of the Optical Unit. Lieut. Colonel Nelson M. Black soon joined him and when he left the office Lieut. Colonel de Schweinitz was put in charge of Ophthalmology and Major William E. Bruner was assigned to duty in the Surgeon General's Office in connection with Ophthalmology.

During Major Mosher's absence abroad Major Charles W. Richardson was put in charge of Oto-laryngology and later Captain Harry A. Barnes was made assistant in this section.

In addition to classifying the officers available for service, the activities of the division consisted in the selection and standardization of equipment, the preparation of a course of instruction in the base hospitals, organization of special schools and laboratories, assisting in the revision of requirements of registrants, the publication of manuals and periodicals and the recommendation of assignments for overseas duty.

Under the head of equipment might be enumerated the following activities: (1) Standardization of instruments and material; (2) Selection of instruments for base hospitals and for special hospital for surgery of the head (No. 115); (3) Selection of equipment of Optical Units; (4) Standardization of spectacle frames and size of lenses for military use; (5) Investigation of possibility of domestic production of glass for artificial eyes; (6) Standardization of an efficient goggle for aviators.

Under the education activities were included: (1) An outline of the course of lectures to be given at the cantonment base hospitals and at the Medical Officers' Training Camps; (2) List of books for libraries at base hospitals; (3) The organization of the special schools at Ft. Oglethorpe; (4) The

compilation and publication of the following books:

1. The Section of Ophthalmology—Manual of Ophthalmology—published by the Government Printing Office.

2. At the request of the Publishing Committee of the Council of National Defense, three members of the Section of Ophthalmology, Cols. Greenwood de Schweinitz and Parker, prepared a Manual of Ophthalmic Military Surgery including chapters on Trachoma and Examination of Malingerers, published by Lea & Febiger.

3. The Section of Brain Surgery prepared a book on War Surgery of the Nervous System published by the Government Printing Office.

4. The Section of Plastic and Oral Surgery revised Blair's book on Surgery and Diseases of the Mouth and Jaw.

5. The Section of Oto-laryngology prepared a Manual of War Surgery on Oto-laryngology.

6. Survey of Head Surgery. A monthly publication.

The following schools and laboratories were established:

1. Officers' School of Plastic and Oral Surgery, Northwestern University Dental School, Chicago, Illinois.

2. Thomas W. Evans' Museum of Oral Surgery, University of Pennsylvania, Philadelphia, Pennsylvania.

3. The Neuro-surgical Schools in Chicago, Philadelphia and New York.

4. The Neuro-surgical, Plastic and Oral Surgical School of St. Louis.

5. School for Medical officers at Ft. Oglethorpe.

6. The laboratory at Baltimore for the investigation of neuro-surgical problems.

7. The laboratory at Ann Arbor for the investigation of peripheral nerve lesions.

The school at Ft. Ogelthorpe was represented by each of the Divisions in the Surgeon General's Office including not only medicine, surgery and laboratory but also the Divisions of Special Surgery. The Department of Ophthalmology was organized by Lieut. Colonel de Schweinitz.

The clinical activities incident to the return of injured soldiers led to the consideration of the appointment of consultants in the various sections of the Division of Head Surgery.

The complete record of the activities of the four sections of the Division of Surgery of the Head would not be of interest at this time so I shall give in detail only those pertaining to the Section of Ophthalmology.

The total number of ophthalmologists sent to training camps, base hospitals in this country and overseas was seven hundred and fifty-nine. Of these, two hundred and eighty were assigned to foreign service. In addition to this number three hundred and sixty-seven were transferred to other service making the total of officers assigned by the Section of Ophthalmology eleven hundred and twenty-six.

During the year several extensive inspection tours to study the work of the Division of Surgery of the Head in a large number of the hospitals of the cantonments of this country were made by Lt. Colonel Black, and less extensive similar tours by Major Harris P. Mosher, Major Allen Greenwood, Colonel Walter R. Parker and Lt. Col. George E. de Schweinitz. The work of Lt. Colonel Lyster and his committee overseas included an inspection of all the American base hospitals in operation at that time (from November 19, 1917 to January 31, 1918), three Red Cross hospitals, one Naval Base Hospital and a number of base and general hospitals in the British service and one French sector as well as the general and special hospitals in England, and

Note: Since reading this paper the following appointments were made Dec. 24, 1918: Consultant in Ophthalmology, Lt. Colonel G. E. de Schweinitz; Consultant in Otolaryngology, Lt. Colonel Harris F. Mosher; Consultant in Plastic and Oral Surgery, Lt. Colonel V. P. Blair, and Consultant in Neuro-Surgery, Major Charles H. Frazier.

a study of the method of caring for blinded soldiers in France and England was made by Lt. Col. de Schweinitz.

An elaborate study of the trachoma question was made from all standpoints by Lt. Col. Black, which included the trachoma hospitals and concentration camps, to observe the work of the U. S. Public Health Service in preventing the spread of disease. A standard test for the detection of malingers who feigned visual defects was compiled by Colonel Parker.

After the standardization of the spectacles to be worn by the soldiers was perfected by Major (now Colonel) Wilmer and his committee, a plan was perfected whereby glasses could be supplied through the Post Exchange at wholesale prices. Later this plan was changed and the government now furnishes the soldiers spectacles gratis.

To meet the demand for spectacles for soldiers overseas a central optical unit was established in Paris with fourteen auxiliary units to functionate as mobile supply stations. A central plant and eight units were taken to France by Major (now Lt. Colonel) Greenwood, who was afterwards made Senior Consultant in Ophthalmology of the A. E. F. and who now has with him as assistants Lt. Colonel Nelson M. Black and Lt. Colonel George Derby.

Pursuant to the authorization of the Surgeon General for the development of the base hospital particularly devoted to surgery of the head to be established in France, a special base hospital was organized at Cape May in February, 1918, was called for overseas duty the 24th of May, 1918, and is now functioning in France with Lieut. Colonel E. C. Ellett as commanding officer and Captain Francis, of Buffalo, in charge of ophthalmology.

The work of the various sections as it is carried out in the base and general hospitals is more or less familiar to all. In closing I wish to speak especially of the complete spirit of cooperation of all who have been associated in this work and of the courtesy and consideration extended to all by the Surgeon General and his entire staff.

SCHOOL OF OPHTHALMOLOGY.

Medical Officers Training Group.

Camp Greenleaf, Ft. Oglethorpe, Ga.

MAJOR MEYER WIENER, M. C., U. S. ARMY.

U. S. GENERAL HOSPITAL, NO. 11, CAPE MAY, N. J.

This paper details the schedule and actual work of the School of Ophthalmology, the organization and development of which was described by Lt. Col. G. E. de Schweinitz (A. J. O., v. 1, p. 817). Read before the College of Physicians of Philadelphia, Feb. 5th, 1919. Authority to publish granted, Board of Publication, S. G. O.

The Army School of Ophthalmology was the outgrowth of plans laid out by our distinguished and able confrere, Lieut. Col. George E. de Schweinitz, who, after several trips to Camp Greenleaf and Ft. Oglethorpe, selected the site, equipment and finally the instructors to direct and develop the school.

I arrived at Camp Greenleaf under War Department orders on July 19, 1918, and started on my course of military training with no idea as to what work I was to do, or where I was to be assigned. On July 30, I was ordered to report for duty to Lieut. Col. de Schweinitz, as instructor in the school of Ophthalmology. The length of the course had already been determined by the proper authorities, to be four weeks, and the hours from 9 to 11:30 and 1:30 to 4, daily, excepting Saturday, when the hours were limited from 9 to 11. Col. de Schweinitz thought from the beginning that the two hours Saturday morning could be taken up to best advantage with written and

oral quiz, and this proved so satisfactory that the plan was continued thruout the life of the school. There remained 25 hours each week, or a total of 100 teaching hours for the course. I was asked to submit a schedule, including two hours of didactic teaching each day, which made a total of forty hours, leaving sixty hours for practical work. After several conferences Col. de Schweinitz finally determined upon a tentative schedule and the school was formally opened on August 12, 1918, with eight student officers. This number rapidly increased, until at one time we were teaching a class of 63 student officers, taxing our facilities to the utmost.

At the time of the organization of the school Captain Alfred Cowan and Lt. L. G. Campbell, then serving in the eye department of General Hospital No. 14, and Lt. M. E. Brownell lent most effective aid and the heartiest cooperation in establishing an efficient course. Later Lt. F. O. Schwartz, Lt. T. J. Moran, Capt. S. T. Hubbard, Lt. Nicholson, Maj. H. M. Morton, Lt. C. P. Dyer, and Capt. Claude T. Wolfe were in turn added to the teaching faculty. Lt. Moran, a brilliant officer of noble character and splendid training, died during the influenza epidemic, his loss being deeply felt by all who knew him.

The following schedule for the month of December illustrates in a measure the course of study outlined for the school, and from this there was very little deviation:

SCHEDULE OF COURSE IN OPHTHALMOLOGY FOR DECEMBER.

FIRST WEEK	*MONDAY*	*TUESDAY*	*WEDNESDAY*	*THURSDAY*	*FRIDAY*
9-10 A. M.	Lecture—Routine of Exam. of Patients—Maj. Wiener.	Lecture—Retinoscopy—Lt. Brownell.	Lecture—Physiological Optics—Maj. Wiener.	Lecture—Functional Testing—Lt. Brownell.	Lecture—Lids and Lacrimal Apparatus. Lt. Schwartz.
10-11:30 A. M.	Practical Work.	Practical Work.	Practical Work.	Practical Work.	Practical Work.
1.30-2.30 P. M.	Lecture—Refraction—Lt. Schwartz.	Lecture—Muscle Testing—Lt. Brownell.	Lecture—Surgery of Lids—Maj. Wiener.	Lecture—Principals of Plastic Surgery—Capt. Davis.	Lecture—Surgery of Conjunctiva—Maj. Wiener.
2.30-3-30 P. M.	Practical Work.	Practical Work.	Practical Work.	Practical Work.	Practical Work.
3.30-3.45 P. M.	Quiz Conference.	Quiz Conference.	Quiz Conference.	Quiz Conference.	Quiz Conference.

(Saturday—9-11 A. M.—Quiz.)

SECOND WEEK					
9-10 A. M.	Lecture—Conjunctiva—Lt. Schwartz.	Lecture—Cornea—Capt. Hubbard.	Lecture—Uveal Tract—Capt. Hubbard.	Lecture—Media and Sclera. Capt. Hubbard.	Lecture—Fundus—Maj. Wiener.

3-4 P. M.	Lecture—Bacteriology and Pathology of Eye—Maj. Keilty.				
3.30-3.45 P. M.	Quiz Conference.			Quiz Conference.	Quiz Conference.

(Saturday—9-11 A. M.—Quiz.)

Practical work in the course includes:

Refraction. Muscle Testing. Outlining visual fields and scotomata.

Examinations of fundi in wards and clinic.

Examination of external diseases in patients in wards and clinic.

Operations on pigs' eyes and on patients in General Hospital No. 14, and in West-Ellis Hospital in Chattanooga. The talks on surgery are illustrated by lantern slides and drawings, and are followed by the operation itself on animal eyes, patients or cadaver.

Also practical paper work in ward and demonstration of method of keeping records and cross indexing.

The purpose of the school was twofold. First, to determine those who were fit for Ophthalmology, from those student officers who had been either held by the Surgeon General's Office for that purpose, or had selected eye work of their own volition. This was done, first, by preliminary examination conducted by the director of the school, who decided whether the student officer had had sufficient ground work to be accepted for the course; and by his final qualification given at the termination of the course as determined by the character of his work, both practical and theoretic, as well as written final examinations.

Second, it served as a postgraduate course for those who would have ordinarily been qualified, but tended to produce even greater efficiency.

The dominant thought prevailing thruout the entire period of instruction was to instill the idea of system in the method of examination of patients and recording of cases; which always, when properly carried, out, makes for thoroness and efficiency.

I wish to state here that the men who stood highest in their profession and proved the most efficient in their work were the ones who were most anxious to take the course and expressed the greatest appreciation for what they got out of it.

One might think that a man's previous experience or standing in the community would be sufficient recommendation, but I can recall one officer who had been practicing his specialty for over twenty years in one of our largest cities, with a preliminary European training, who could not even be accepted in the school, altho on account of his years I endeavored to be most liberal and lenient with him. One officer who had been commissioned a major and who had limited his practice to diseases of the eye, did not answer one single question given him on preliminary examination. Another, who had a flourishing practice in one of our large industrial centers and was teaching Ophthalmology in an accredited university, passed such a poor examination, that we could not accept him for the course. In this particular case where the applicant had been giving special instruction in refraction, he was unable to transpose a prescription for glasses, did not know the action of the ocular muscles and did not realize the influence the mus cle balance had in determining the amount of refractive error to be corrected.

I may mention, that in all doubtful cases, the entire staff was consulted as to the disposition of the particular officer, and that I have access to a file containing the record of each question and the answer given by every student officer examined, should any question come up as to the justice of our decision. Occasionally, when there was some doubt as to whether a man might make good or not, he was given the benefit of the doubt, and taken into the course on trial. If he proved to be unworthy, at the end of a week or so, he was sent back for general duty; if he made good, he continued in the course. A few finished who were able to do careful and excellent refraction work, but whose general work otherwise did not come up to requirements. These were recommended for refraction only. Others who showed unusual proficiency in operative work were recommended accordingly. An unusual opportunity was offered to grade the officers, as each case examined by them was checked up by one of the staff, and every Saturday the entire class was quizzed for one hour by the director, and then in sections by the rest of the staff. On the last Saturday of the course a written quiz was given, one question or more being asked on each of the following subjects: Anatomy, Pathology, Optics, Refraction, Muscles, Diagnosis, Treatment, Ophthalmoscopy, Neurology, and Operations. Each week a conference was held by the staff, the grades of all the members of the class written down by each instructor and submitted to the director. It was surprising how closely these grades coincided, and it was seldom that there was enough difference to even bring up a discussion. When a name came up on which there was a wide difference of opinion by the several members of the staff, his name was recorded by the staff and his work observed more closely than before by all of us. In this manner a satisfactory agreement was always reached.

One interesting feature which developed during the later stages of the school was the quiz conference. It was found that usually the officer finished the case given him to work out in the afternoon fifteen or twenty minutes before closing time and there would be a grand rush to get thru and hasten back to the barracks. We therefore compelled the entire class to assemble the last fifteen minutes of the day and devoted the time to having the student officers ask questions of the instructors on any point which might have come up during the course of their work during that day. This gave rise at times to most interesting, and I think, instructive discussion in clearing up any hazy impression.

The close contact into which I was thrown with such a large number of men practicing the eye as a specialty, impresses me most forcibly with the necessity for a more thoro and sys-

tematic course of training for the specialist.

For our own department, I have thought that some of the heads of the ophthalmologic departments of our leading medical schools might get together and outline a plan for a course of instruction whereby anyone desiring to take up this specialty could be assured of an efficient and effective course of training making for proficiency. I am also convinced that as a fitting climax, each one should strive to secure a certificate from the American Board of Ophthalmic Examiners, as a mark of his capability. I am convinced that this certificate should never be given, as is occasionally the case at present, to a man on his reputation or standing in the community, but that there should be no exception, and anyone desiring this certificate should submit to the same sort of examination.

I believe the leading Ophthalmologists of the country should set an example and express their willingness to cooperate by submitting to this examination, whereby the actual worth of such a certificate would be increased many times and make its possession a goal for which one should strive.

REFRACTION METHODS EMPLOYED IN THE DEPARTMENT OF OPHTHALMOLOGY OF THE ATTENDING SURGEON'S OFFICE, UNITED STATES ARMY, WASHINGTON, D. C.

Major John R. Newcomb, M.C., U. S. Army.

INDIANAPOLIS, IND.

This paper describes the methods in question with especial emphasis upon objective methods, a subjective test for astigmia, the card record kept of each case, and the use of a cycloplegic followed by a miotic. Authority to publish granted by the Board of Publications, S. G. O.

The accurate determination of errors of refraction offers to the ophthalmologist a field which, until recent years, has been more or less neglected and which warrants the very best efforts of every man engaged in ophthalmology. The reason for the dislike and frequent neglect which so many ophthalmologists exhibit toward refraction work is due to but one thing and that is the fact that refraction work has not been done scientifically, the element of chance having played a major role, and the ophthalmologist being a scientifically trained man naturally feels a dislike for that phase of his work which presents to him little other than the humdrum, "Is this better or worse?"

Leaving the selection of a lens to the patient's judgment discounts at once the value of any scientific observations which may have been made. The moment the psychology of visual judgment enters as a positive element into the determination of the lens to be prescribed, just that instant the ophthalmologist fails. Frankly or perhaps subconsciously he admits to himself that his work is not good, that luck is in reality the determining factor in the selection of lenses; and that, no matter how he may temper the patient's visual judgment with his own opinion and experience, the result is and always will be largely a matter of luck. Unfortunately, reference to the patient's visual judgment cannot always be wholly eliminated but it can be made to assume a very minor role.

One thousand consecutive refraction cases have been taken as the basis of the statistic feature of this report. The first one thousand patients under forty years of age have been selected and represent a great variety of professions and occupations. A very small proportion of these patients was com-

posed of others than officers and enlisted men of the army. The statistics are compiled from the case records written by the four officers on duty in The Department of Ophthalmology of The Attending Surgeon's Office; and, are, therefore, of greater value than had they been based upon the work of but one man. My associates, Captain W. H. Chandlee, Lieutenant B. J. Larkin and Lieutenant W. J. Creighton have assisted in every way to insure the accuracy of the records.

An analysis of the first one thousand cases of error of refraction shows the various errors to have occurred in the following percentage of frequency:

Emmetropia	0.5%
Simple Hyperopia	8.5%
Simple Hyperopic Astigmia	5.7%
Compound Hyperopic Astigmia	45.8%
Simple Myopia	3.5%
Simple Myopic Astigmia	3.3%
Compound Myopic Astigmia	16.9%
Mixed Astigmia	15.8%

In comparison with previous statistical reports published the percent of emmetropia is higher; due, doubtless, to the fact that these patients represent, as a class, men whose physical condition was of necessity above the average.

Sixty percent of these patients present hyperopia or its astigmias and the the myopic astigmias are represented by 23.7 per cent. Mixed astigmia is less than I have reported in previous papers being found in but fifteen and eight-tenths percent. This decrease is probably due to the fact that the men presenting the high degrees of mixed astigmia possessed insufficient visual acuity to permit their entering the army and therefore did not come under the observation of this department.

The method of examination will now be described in detail with the hope that the routine methods of this department may show an effort toward more scientific refraction, and that the skeptical may be induced to try to substitute objective for subjective methods. The objective method of refraction is not yet perfected, but with its few imperfections it is far more reliable and infinitely more scientific and accurate than the best of the subjective.

History. The history card illustrated has proven satisfactory in the recording of all necessary information and with but few changes may be made available for use in private practice. Its advantages are simplicity, brevity and practicability. The use of this card is explained by reference to the illustration.

A normal fundus is indicated by outlining the optic nerve and printing within the circular outline of the nerve the letter "N." Should abnormalities of the fundus be discovered, the words, "See Reverse" may be written within the circle and a drawing and description of the ophthalmoscopic findings made on the reverse side of the history card.

The skiascopic findings are recorded within the large circle as shown in the illustration and the axis, as determined in the dark room, indicated by drawing a line in the corresponding position of the axis of the correcting cylinder. The advantages of using this method of recording ophthalmoscopic and skiascopic findings are that the maximum of information is condensed in small space in the minimum of time and that a glance at the history card immediately gives the desired information.

The reverse side of the card is blank and may be used for drawings or extended notes. On this card of four by six inches all data relative to the average case can be quickly, accurately and comprehensively recorded without unnecessary waste of space.

Vision of each eye, with and without lenses, is recorded; extraocular muscle balance, (E.O.M.), determined and the tension of each eye recorded.

In eliciting the history of symptoms it has been found advisable to follow a definite outline of questions. The nurses on duty take the history and in a general way follow the scheme of questions here outlined.

1. How long have you worn lenses? Present correction how long?
2. In what way do your eyes trouble you?
3. Where is the headache usually located? (The location of headache is recorded in the

history as frontal, supraorbital, postorbital, temporal, vertical, occipital or nuchal, the so-called "check-rein" sensation.

4. Do you have pain in your eyes? Sharp or dull? Does it follow close work? Is it present following theater or church? Does it come at any particular time of day?

5. Do your eyelids smart or burn? Is there any secretion present in the mornings?

6. Does the light hurt your eyes?

7. Is your sight poor for distance or for close work? When did you first notice this, and has it become worse slowly or rapidly?

8. Have you noticed anything peculiar about lights at night? No rainbow or halo?

9. Are you subject to nervous depression or to nervous irritability? How does it manifest itself? Do you have difficulty in going to sleep? Do you have peculiar "floating sensations" when you first lie down? Do you have vertigo?

10. Unclassified symptoms.

Needless to say the nurse does not necessarily ask all these questions, for usually when the patient is given opportunity he will recite his train of symptoms without questioning or prompting. However if the above outline is borne in mind a few additional questions will usually suffice to complete the record. The recording of the symptoms presented by the patient is very valuable, and is of great assistance in the guidance of the patient subsequent to the examination.

The history having been completed, and there being no increased tension nor history suggestive of a glaucoma or of a glaucomatous tendency, the cycloplegic is instilled. In this office a solution of homatropin hydrobromat 2 per cent, and erythroxylon hydrochlorid 1 per cent is used for the induction of cycloplegia. One drop of such solution in each eye at ten minute intervals for five instillations is sufficient and the ciliary muscles are relaxed at the end of sixty minutes. There are rare exceptions to this. The ideal method of using this cycloplegic is in the form of B. W. ophthalmic discs, each disc containing one fiftieth of a grain of each drug. These discs have not been obtainable during the war. One of these discs placed on the conjunctiva of the lower lid near the outer canthus will produce a cycloplegia equal in degree to that brought about by the use of five drops of the solution and there does not exist the danger of systemic effect.

Whichever is used it is of the utmost importance that pressure be made to exclude the drug from the nasal

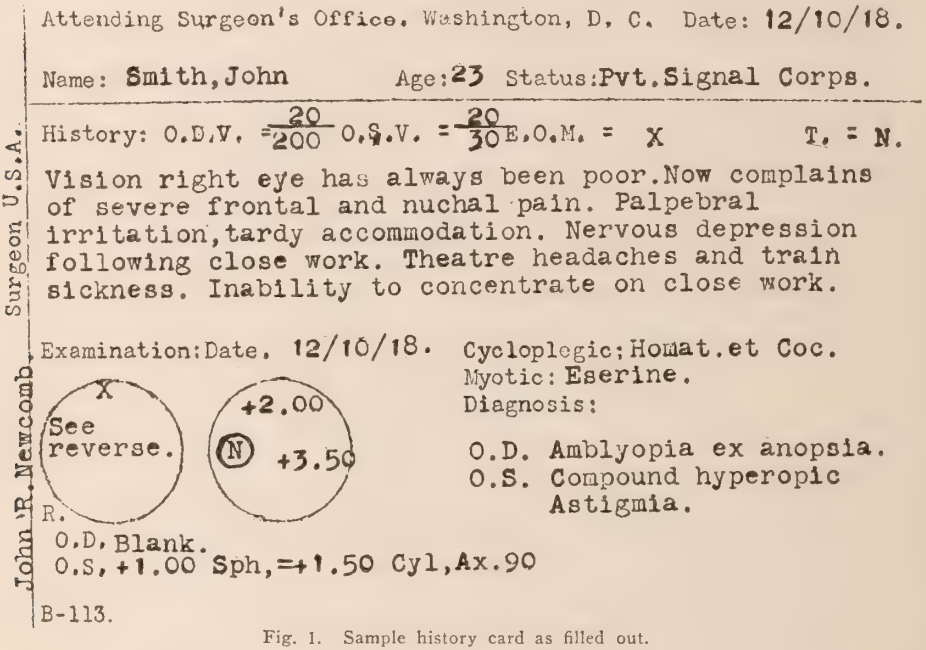

Fig. 1. Sample history card as filled out.

passages. After sufficient time has elapsed for the complete absorption of the drug by the ocular tissues, about five minutes, it is neither necessary nor advisable for the patient to continue the pressure against the side of the nose or to keep the eyes closed. Care must be taken . . . in every case to insure the establishment of cycloplegia as well as mydriasis.

Ophthalmoscopic Examination. It seems needless to mention that a careful ophthalmoscopic examination should be made of every case refracted. However a surprisingly large number of patients who have previously been examined by oculists have stated that no ophthalmoscopic examination had ever been made in the previous examinations. The electric ophthalmoscope has been found superior in all ways and possesses advantages too numerous to mention.

Skiascopic Examination. This is by far the most important phase of the examination and skiascopy is an art which can be mastered only by persistent and unlimited practice and constant practical application. The choice of skiascope is important. The most satisfactory instrument to use is equipped with a plane mirror of 18 mm. diameter, the mirror being preferably of Noviol glass, and the mirror should be tested to insure its being a true plane mirror. Irregularities in the mirror surface will lead to faulty results and this is frequently the cause of unsatisfactory results in the skiascopy. A second skiascope of but 10 mm. diameter has been found advantageous but it requires a great deal of practice with so small a mirror before the use of it becomes satisfactory.

The source of light is very important and in this office the most satisfactory light for skiascopy has been obtained from a 60 watt frosted bulb Mazda lamp such as can be obtained from any dealer in electrical supplies. The lamp should be so jacketed as to keep all light off the patient's face. It should be placed between the patient and the operator on a level with the eyes.

The one meter distance between the eye under examination and the skiascope is of utmost importance and great accuracy in maintaining this distance is to be observed. A variation of one or two inches is inconsequential but beyond this slight variation error is certain to result. It is not necessary to employ any mechanical means to maintain this distance as any such appliance is apt to prove annoying and cumbersome. White marks on the black wall of the dark room indicating the distance of one meter make possible the correct placing of the chair for the patient and the stool for the operator.

Skiascopy with trial frame and lenses: The use of the so-called skiascopic frames is not to be recommended as their use leads to hurried, careless methods and the determinations made are gross determinations and merely approximate the actual correction. Experience has shown that the skiascopic correction of first one principal meridian with a spherical lens and then the correction of the opposite principal meridian with a sphere does not give accurate results in the correction of an existing astigmia. This is very frequently demonstrated in using sphero-cylinder combinations in the skiascopy in the dark room, it being no uncommon thing to find it necessary to change the sphere originally selected when the proper correcting cylinder is superimposed. For example, if a plus one seventy five sphere is found to stop shadow movement in the vertical meridian, but is insufficient for the horizontal; and an additional seventy five cylinder, axis ninety degrees, corrects in the horizontal it is frequently observed that the original sphere of plus one seventy five must be reduced to a one fifty or even less. Had the correction been done with the skiascopic frames the reduction in strength of the sphere for the vertical would not have appeared necessary, and the result would have been an overcorrection in all meridians. For this reason, if for no other, the use of the skiascopic frames is to be heartily condemned. It is the ob-

servation of this office that the use of trial frame with sphero-cylinder combinations in the performance of skiascopy leads to far greater accuracy in results and its use is recommended. The Punktal trial case with the small lenses, and the trial frame or portable phorometer supplied with it, make an ideal equipment for skiascopy. The increased initial expense is more than offset by the very many advantages offered by its use.

The determination of the axis of an existing astigmia is most often made in the dark room examination. This is true only when the skiascopy is done with the trial frame and sphero-cylinder lenses. Practice will enable the operator to determine with the greatest accuracy and ease the axis of astigmia, and recourse to subjective methods is very seldom necessary. To those who are exponents of subjective testing this may meet with disapproval; but the fact remains that such a determination is possible and that in this office subjective methods of determining axis are not resorted to in over five percent of all cases refracted.

Skiascopy can no more be described than can the correct playing of the violin; and the technic of skiascopy can only be mastered by hard, patient, studious effort. Several points, I wish to emphasize. First, that the movements of the mirror should be very limited. A tilt of the mirror of four millimeters is usually all that is necessary or advisable. In some cases this range of mirror excursion will have to be extended but it will be found with practice that the mirror movements can be materially reduced in range. One of the most confusing complications of skiascopy may be brought about by too extensive mirror movements. Tilt the mirror just enough to bring out the true shadow movement and a considerable confusion will be avoided. Second: The establishment of the proper distance between the patient's eye and the skiascopic mirror. This should be one meter. Third: The use of a small skiascope is absolutely essential for accurate results. A mirror of 18 mm. is as large as should be used. Fourth: Proper illumination as described. The electric skiascopes are not good because of the fact that an uneven illumination apparently is not avoidable. In connection with the subject of illumination it should be mentioned that the dark room should be a dark room and not a darkened room. The less outside light entering the room, the better the skiascopy.

Only by recognizing skiascopy as being very difficult of mastery and by hard, diligent practice and observance of all the details of technic can skiascopy be made to serve as it should. Proper application of skiascopy furnishes us the ideal method of determining errors of refraction and the application of proper correcting lenses and if carefully and accurately done it will be found that in most examinations the prescription for lenses may be written directly from the dark room findings without recourse to the subjective methods of examination. This claim will doubtless meet with opposition but such opposition will arise from those who do not perform skiascopy accurately, and from those who do not have faith enough in their dark room work to trust to its practical application in the formulating of the prescription for lenses.

SUBJECTIVE TESTS.

The determination of the axis of astigmia is not always possible in the dark room examination and subjective tests must occasionally be resorted to. Subjective tests for determining axis are numerous and none without its faults. The criticism to be offered concerning the majority of astigmia charts is that they are confusing and that the patient is allowed too great latitude in the formation of his visual judgment. The chart in use in this office possesses faults but its one recommendation is its simplicity which in turn means its greater accuracy. All tests for the determination of axis of astigmia should be made while the patient's eyes are completely under the effect of the cycloplegic and the findings thus made should not be altered, regardless of what the patient's judgment may

seem to indicate, in case a postcycloplegic test is made. Adherence to this point is absolutely necessary and deviation from it means failure.

The astigmia chart employed in this office is illustrated below. It consists of black and white squares, 15 by 15 m.m., alternately placed in the form of a checkerboard. The chart is twenty-four centimeters in diameter and circular in form.

The chart is used at a distance of twenty feet from the patient or at a lesser distance if more convenient or if necessary on account of reduced visual acuity. The patient's eyes being under a cycloplegic and the spherical lens being in place in the trial frame, the proper correcting cylindric lens is placed in the frame at the opposite axis to that which was found in the dark room to be correct, or approximately correct.

Fig. 2. The checkerboard chart as seen by the emmetropic eye.

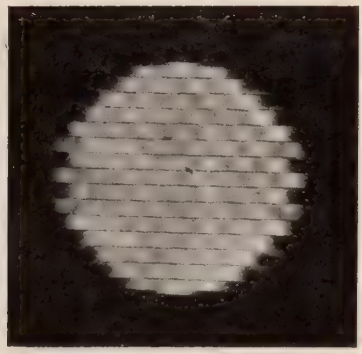

Fig. 3. Checkerboard chart as seen by an eye with simple myopic astigmia of one diopter, axis 90°, the accommodation being entirely relaxed.

Before this lens is placed in position, in the faulty position described, the patient is advised that the addition of the cylinder will result in a very decided blurring of the checkerboard. In the words of the patient, "the squares are all mussed up." Having demonstrated this to the patient, slowly turn the cylinder, having instructed the patient to say, "stop," so soon as there appear clean cut black and white squares. With children this test may readily be turned into a game into which they enter with marked enthusiasm. There is rarely any hesitancy on the part of the patient when the proper axis has been reached, and repeated rotation of the cylinder will prove the accuracy of this test, as the patient will not vary in his selection of axis. The thing is so very simple that almost without exception there is present no confusion on the part of the patient and a repetition of the test is seldom necessary. The test is recommended as being most accurate on account of its simplicity and its use will eliminate much needless confusion and will result in a great saving of time. Its use as compared with the clock-dial and other astigmia tests will very quickly and conclusively prove its superior value.

The following illustrations will demonstrate as clearly as photographs can the principle of this test. The camera is made astigmatic by the addition of a cylinder to the lens system. By adding a plus one cylinder at axis 180° the camera is made myopic to the extent of one diopter in the vertical axis. In other words a simple myopic astigmia is produced. The correcting cylinder, a —1.00 is next introduced into the lens system at right angles to its known proper axis, i.e., at axis 90° instead of at the correct axis of 180°.

Postcycloplegic examinations are sometimes necessary in addition to the dark room findings. As has been stated the postcycloplegic examination is the exception in this office, and when made is really but a verification of the

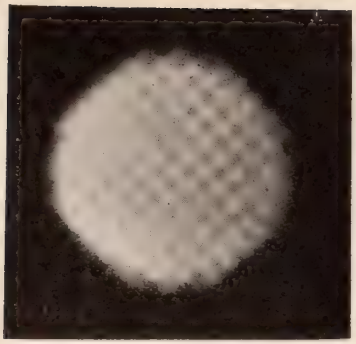

Fig. 4. Same refractive condition as above illustrated with the correcting cylinder placed at 90° instead of at 180°, the proper correcting axis.

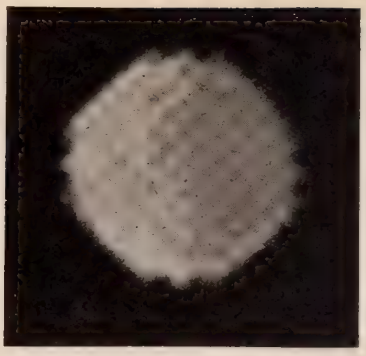

Fig. 5. Correcting cylinder placed 45 degrees from correct position.

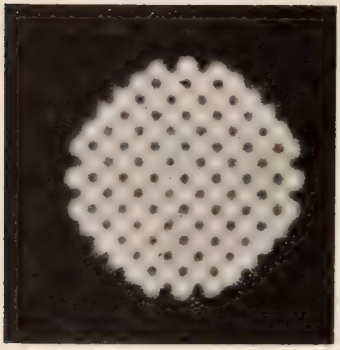

Fig. 6. Correcting cylinder placed 30 degrees from correct position.

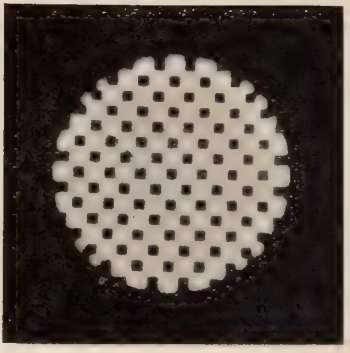

Fig. 7. Correcting cylinder placed 15 degrees from correct position.

Fig. 8. Correcting cylinder placed 5 degrees from correct position.

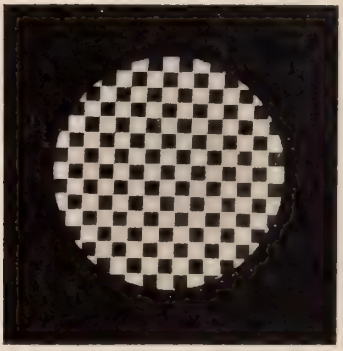

Fig. 9. Correcting cylinder placed 1 degree from correct position.

dark room findings and not a postcycloplegic examination in the broad sense of the word. This is not omitted in an endeavor to save time, but experience has shown these subjective tests to be superfluous in the majority of cases. The postcycloplegic tests for spherical tolerance and axis are made only in those cases in which the axis of astigmia has not been absolutely determined with the skiascope; and in such cases as present an error of refraction of unusually high degree, particularly if the patient has not had previous experience with lenses. The reason for this is obvious. It must again be emphasized that the dark room findings are not deviated from, there being no digression from the actual findings, and the patient is given no opportunity to detract from the value of a scientific refraction by giving his unreliable and capricious opinions.

The routine use of a *myotic* has been both advocated and denounced; and yet the fact remains that it furnishes us with a most valuable aid, and should be used invariably and without exception following the use of a cycloplegic, in all patients over sixteen years of age. In children its use is not to be advocated on account of the very severe and intense ciliary spasm which is apt to result. In adults this is a very rare thing, but one case having been observed over a period of eleven years constant use. It is a grave mistake for an ophthalmologist to permit a patient to leave his office under the effect of a cycloplegic except in those cases where there exists a therapeutic reason for its continued action.

As before mentioned the ophthalmic disc furnishes the ideal method of application, but during the period of the war it was necessary to revert to the use of the solution. One drop of a one percent solution of eserin sulphat placed in each eye will speedily restore the accommodation with no unpleasant effects arising from its use. Previous to its instillation the patient is warned of the slight muscular twitching and spasm of the palpebral muscles which persists for a few minutes.

The advantages obtained from using the myotic are, first, safety. A glaucoma will not be a possibility. Second: Patients are enabled to return to any close work within an hour after leaving the office. There are rare exceptions to this. Very frequently the ciliary function is restored in even less time but in some conditions it is two to three hours before the full effect is gained. This varies according to the error of refraction present, the hyperopic eye requiring more time and the myopic less.

In the prescribing of lenses it may be well to mention that all prescriptions from this office call for *spectacles,* except in cases of simple hyperopia or myopia. If sufficient time is taken to explain to the patient the absolute necessity of having the glasses straight there will be found but little opposition to the wearing of spectacles. When patients remain obdurate it is wise and advisable to refuse to accept responsibility for the unsatisfactory results which are sure to follow the wearing of a cylindrical or sphero-cylindrical lens in any other than a rigid spectacle mounting. After the patient has become accustomed to the spectacles there is no objection to nose glasses for evening wear, for once the eyes have become comfortable following the use of the spectacles the inaccuracy of the nose glasses will speedily be reognized by the patient, due to the return of symptoms.

It has been the purpose of this report to emphasize the importance of observation of all details of refraction work if a uniformity of results is to be expected. It has been possible to dwell upon only a few of the more important features of the work in this report and those selected are the points upon which most ophthalmologists are at variance. The most painstaking examination will be unsuccessful if all the details of technic are not rigidly adhered to thruout the entire course of the examination.

The application of the method of routine refraction which this report has

attempted to discuss may well be adapted to use in private practice without change of material importance. It has been the method followed by the author for eleven years in private practice and the results obtained have proven the reliability and dependability of the objective method of refraction. My associates in the Attending Surgeon's Office have adopted this method of objective refraction; and with the opportunity offered for observing the final results obtained in the refractions performed in this office, it may be said in all fairness that the objective method of determining and correcting errors of refraction has proven itself to be superior in every respect to subjective methods. The proof has been so convincing and conclusive that all subjective methods have practically been discarded, and the refraction work of the Department of Ophthalmology of The Attending Surgeon's Office is based entirely upon objective methods.

FUNDUS PATHOLOGY WITH THE RED-FREE LIGHT OF VOGT.

ROBERT VON DER HEYDT, M.D.

CHICAGO, ILLINOIS

This paper calls attention to (a) A new Symptom of Retinal Atrophy, and (b) Macular and Foveal Changes. With illustrations showing the apparatus used to furnish the light. Read before the Chicago Ophthalmological Society, February 17, 1919. (See p. 351 for Discussion.)

In the normal fundus the red-free light gives us the first absolute demonstration of the yellow coloring at the macula in the living eye. Owing to an increased contrast new details of the macula and fovea can be seen.

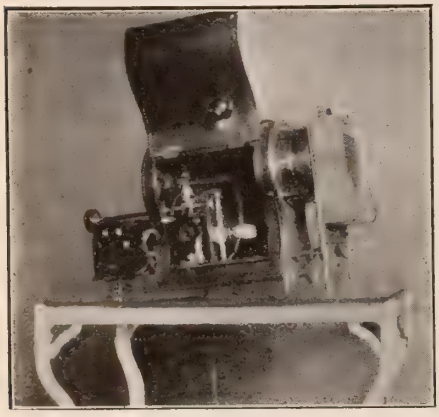

Fig. 1. Lamp with filtration apparatus, after Vogt and Affolter.

With it we can also measure by comparison the yellow discoloration of the lens in age and in monolateral aphakia.

In addition the increased visibility of the retinal nerve fibers with the red-free light is of great importance. In a recent article Vogt draws attention to the fact that optic atrophy with our present method of examination is only diagnosable at the nerve-head and from the vessel caliber of the same. The retina, however, though it no doubt is regularly involved in the atrophic process, shows no ophthalmoscopic changes. With the red-free light he is able to see the nerve striations of the retina and study their pathologic changes.

In optic neuritis and retinitis the nerve fibers are coarser, single bundles intermingle, while elsewhere they are interrupted and seem to recede in step-like layers.

Aside from these inflammatory changes he finds certain modifications of the nerve fiber striations in optic atrophy. In complete postneuritic, as well as in primary and glaucomatous atrophy, also in that complicating retinitis pigmentosa and fracture of the base of the skull, there is found a white, marble-like mottling of the surface.

Most interesting and instructive are the cases where one optic nerve is normal and the other atrophic.

A case of this type, following fracture of the base of the skull, five years ago, in a male, now forty-five years of age, is described.

With the ordinary illumination there are no changes except those of atrophy at the nerve-head and its vessels. With the red-free light, however, we find a total absence of the retinal striations in the atrophic eye. In their place there is a delicately mottled marbleized surface. Also, a thin, whitish line on either side of the vessels, invisible with ordinary illumination. In a case of partial postneuritic atrophy complicating multiple sclerosis there was a reduction in the visibility of the nerve

Fig. 2. Honey-comb appearance of macula.

fibre striae, and in certain zones they were absent.

This herewith described disappearances of retinal striations must be added to the symptomatology of optic atrophy, and must be conceded to be the only known visible ophthalmoscopic sign of retinal atrophy, if we exclude the more or less indefinite picture of shrinking of the vessel caliber. Of especial practical importance are further detailed observations made with the red-free light in retrobulbar neuritis.

In the diagnosis of this quite common and often obscure eye disease, we must at times make absolute dependence on such subjective symptoms as the statement of the patient as to his habits, nyctalopia, central scotoma, etc.

Several authors have drawn attention to degenerative changes in the retinal vessels which accompany this disease. They are, however, not always present and often difficult of diagnosis. If present they are not necessarily pathognomonic of retrobulbar neuritis. The latter is also true of the so-called temporal pallor of the disc, which is often found in normal fundi.

It is therefore of great practical value that we have in the red-free illumination a method at our disposal with which we can diagnose degenerative changes of the maculopapillary bundle in retrobulbar neuritis.

The changes found with great regularity (eight cases) are the above described absence of striation and a substitution therefor of the marbleized zone in the papillomacular bundle.

Vogt has been able to observe similar changes and degenerations in this same retinal zone in cases of ascending atrophy of this central nerve tract in isolated disease, and degeneration of the macular and foveal zone.

Very recent anatomic investigations have proven that the macular zone is practically absent in the eyes of Albinos. The investigations of Vogt and Affolter seem to confirm this as they fail to find the yellow coloration at the macula in the eyes of living Albinos. This leads to the conclusion that the absence of the yellow coloring matter deposited in the macula is in direct or indirect relation to the lack of pigment in general.

In the past few months I have been able to study many fundi with the red-free light. The yellow coloration of the macula is most beautiful. I note a greatly increased visibility of the foveolar reflex of Dimmer. It shows as a most luminous spot, much more glistening, for instance, than any so-called cholesterin crystals I have ever seen.

Further investigation in this zone with the red-free light I am sure will make of greater value the work of Haab, Dimmer, Gullstrand, and others who have made this physiologically so important, and pathologically most vulnerable retinal area, the object of

so much observation, study and research.

Vogt describes certain pathologic honeycomb-like changes of the macula, visible only in the red-free light. They were found especially in cases of retinitis pigmentosa, and continued during certain long periods. A year later, in one case, he found them less marked. In other very advanced cases they were absent.

Vogt also has noted this vacuoli formation, for a period of several months, in cases of injury to the macula following contusion of the bulb. Later on they gradually disappeared. He considers them symptoms of vascular and cystic degeneration of the macula.

Leber has described similar vacuoles of the macula anatomically and presumes that the bursting of some of their thin anterior walls could produce, in time, the condition we know of as "hole in the macula."

Vogt gives a most interesting description of vacuoles of this kind in a case of embolism of the central retinal vein. Two large, nearly circular, spaces in the center of the macula showed a hyphema in their lower thirds. After a few days these two became confluent. Quite a number of other smaller vacuoles, partly containing blood, were visible and remained so for months. If the patient would be examined lying on one or the other side, this precipitate would slide or gravitate to the altered position. On the patient's resuming the upright attitude they would return to their original site in about two minutes.

Following this experiment a distinct clouding of the clear contents of the cyst above the hyphema was repeatedly noted and continued for a short period, due to a whirling or stirring up of the pigment disturbed in its complete precipitation.

All of these observations prove that cystic degeneration of the macula can produce the condition we call "hole in the macula," and account for the great length of time so often consumed in gradually bringing about this interesting pathologic condition.

Fig. 3

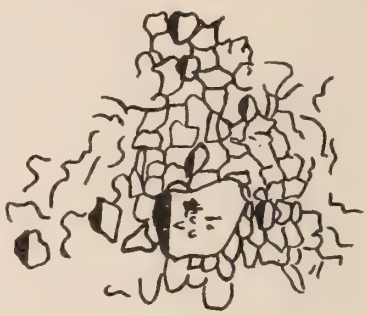

Fig. 4

Effect of change of posture showing gravitation of hyphemae.

Many new reflexes in various parts of the retina and true folds not due to separation or detachment are fully described by Vogt in several recent articles. Affolter also emphasizes the greater visibility of delicate vitreous opacities, deposits on lens and vascularization of the cornea, with the red-free light.

It is not expected that this method will supersede the ordinary light for ophthalmoscopy. Certain conditions, such as exudative zones, the changes of retinitis proliferans, medullated nerve fibers, and the star figuration of retinitis, for instance, are seen in better contrast with our old light. There is no doubt, however, that with the red-free light we have added a most valuable and helpful method of diagnosis.

NOTES, CASES AND INSTRUMENTS

FOREIGN BODIES IN THE EYE BALL—THREE ILLUSTRATIVE CASES.

JOHN J. O'BRIEN, M. D.

SCHENECTADY, N. Y.

In the literature and in the books we often look in vain for positive, clearcut guidance in difficult problems presented to us. For this reason, the subjoined narrative of types of some common but serious eye injuries may not be without value in helping to form a judgment, upon the correctness of which a life of light or darkness may hang.

CASE I.

In September last, J. M., aged 50 years, was reaming holes in a locomotive boiler in the local plant of the American Locomotive Company. Reamers are made from very hard steel. As the tapered end of the one he was using would not enter the hole, he hit the other end with a hammer. A piece of the brittle steel flew and penetrated his right eyeball 7 mm. to the nasal side of the limbus and 3mm. below the horizontal meridian.

Within an hour after the accident, the foreign body was located by X-ray 14 mm. back of the cornea, 2 mm. from the retina on the temporal side and 5 mm. below the horizontal plane. The particle was 3x3x1 mm. With a magnet the steel was extracted from the globe thru the wound of entrance. There was a little reaction without, but considerable haziness of the vitreous within the eye. On the 17th, the vision was 7/200 and no details of the fundus were visible. Within a week, as there was no pain and the external inflammation had completely subsided, the man insisted on returning to work, which he did. From this time to the present there has been no pain nor other untoward symptoms. He was put on 5 grains of K. I. in a glass of water t. i. d. The haziness of the vitreous slowly cleared, so that now but a suggestion of it remains. The retina, vessels and papilla are normal and the vision without lens is 20/15 partly.

CASE II.

In July, 1918, J. S., while passing about ten feet away from a man who was chipping a steel casting, was hit in the left eye by what was supposed to be a piece of the chisel. Half an hour after the injury, the eye was quiet and showed a 5 mm. cut thru the conjunctiva and sclera, 12 mm. from the limbus and just below the external rectus tendon. The conjunctiva was loosened and so sutured as to cover the wound in the sclera. Ophthalmoscopic examination showed nothing abnormal; nor did the appearance of the eye suggest a serious injury. The patient was sent home.

An hour later the shop hospital telephoned that there was probably a piece of steel in the eye, so the patient was at once sent for an X-ray examination. The roentgenologist reported a foreign body 1x1½x½ mm. in the vitreous, 5 mm. anterior to the macula lutea. The same day the sutures were removed from the conjunctiva and a magnet applied to the wound. The foreign body was not recovered. An X-ray on the following day showed the foreign body in the original place. Another attempt to extract with the magnet was again a failure. The reaction from this second attempt was severe, so the eye was allowed to quiet. A third X-ray picture by a different roentgenologist was exactly like the two prior ones. A consultant agreed that if the foreign body was not recovered after another trial with the magnet the only safe procedure was enucleation. To this the patient and his parents consented. Another trial with the magnet resulted in another failure. The eye was removed. A most careful autopsy on the eye failed to discover any foreign body. But a subsequent X-ray of the orbit showed

the same foreign body in the same place. It had not entered the globe at all but had passed between the conjunctiva and sclera and lodged in the orbital tissues immediately adjoining the globe.

The roentgenologist of the Manhattan, Eye, Ear and Throat Hospital willingly told me how to avoid a like tragedy in future: Suppose the exposure for the picture is ten seconds. For the first five, have the patient look straight out, then have him change the direction of the visual axis by rolling the eye up as much as possible and complete the exposure. Make another exposure but do not move the eye. If the foreign body is in the globe, the X-ray will show either two bodies or an extension in the direction of the movement of the opacity as compared with the latter picture. When the foreign body is in the orbit or adjacent tissues its position is not affected by any movement the eye will make. There is, however, a slight possibility of error when the foreign body is in an external ocular muscle or tendon. Then it will show some displacement but a careful reading of the picture will discover the true meaning.

CASE III.

Late in the spring of 1918, a boy of twenty was hit in the left eye by a small piece of gunmetal. It penetrated the cornea, iris, lens; and the X-ray showed it as if in the posterior capsule of the latter. The following day the lens was extracted in the hope of removing, with it, the gunmetal. Another picture showed the gunmetal in the original position. A month later an effort was made to remove the foreign body by washing the anterior chamber, using considerable force, but with no better result. The eye recovered so that in a few days it was quiet.

The patient and his father were advised that the safety of the right eye lay only in removing the injured one. They did not take kindly to this advice and consulted another oculist, who took charge of the case. The latter found a nasal sinuitis, treated it and also operated on the eye, with what he believed a very happy result. Two and a half months after the accident the young man was about to be discharged from the hospital when the right eye became inflamed. Prompt enucleation of the exciting eye had no beneficial effect whatever. Notwithstanding the best hospital care and the most approved energetic therapeutic measures, the vision in the right eye dropped to bare light perception, and so remains.

A considerable experience with foreign body cases has convinced the writer that among the very worst are these where copper and its alloys enter within the globe. Failure of prompt removal of the foreign body should at once be followed by enucleation if disaster is to be averted and a tragic ending avoided. Should one be tempted to gamble with fate, or from any motive fail to sacrifice an eye that is, or almost probably will be blind, the associated memories that persist in hovering about such a case are certainly not pleasurable, whatever profit they may give as experience.

CONVERGENCE INSUFFICIENCY AS IT AFFECTS THE RETURNED SOLDIER.

C. E. Hill, M. B.

TORONTO, CANADA.

Men entering the American and Canadian armies were, perforce, examined rapidly in so far as an ocular examination was concerned. This, I infer, would be more noticeable in the Canadian than in the American army, as the call for men was so urgent in 1914 that many men with poor vision slipped thru; and it is needless to say that practically no man was examined for the refined errors of refraction, muscular imbalance and the allied ocular troubles, provided each eye separately had vision equal to the then existing standard. These men, who have been living under new conditions and working in the varied theaters of the war and in all branches of the service, are now returning, and are receiving a thoro examination at the demobiliza-

tion centers before returning to civil life; and it behooves the oculists to see that these so-called minor, but nevertheless very troublesome conditions be recognized and treated accordingly.

In the examination of many hundreds of returned men my attention has been called to the oft repeated complaint, viz.: "I can only do near work, such as reading and writing, for a very short time when suddenly my vision becomes blurred and the lines seem to run together." Following the teaching of Dr. Alexander Duane, I hurriedly ran these men thru the various tests for convergence insufficiency, viz.:

First. Near point of convergence denoted by Dr. Duane as P. C. B.

Second. Screen test for near and far, parallax taken at the same time.

Third. Prism converging power.

Fourth. Prism diverging power.

Fifth. Testing the eyes in the various positions covering one eye then the other.

A. In the primary position at eighteen inches.

B. Eyes looking up and to the right.

C. Eyes looking up and to the left.

D. Eyes looking up in the median line.

E. Eyes looking down in the median line.

F. Eyes looking down and to the righth.

G. Eyes looking down and to the left.

H. Eyes looking to the right.

I. Eyes looking to the left.

These tests are rapidly done and they show at a glance if it is a muscular or an associated movement anomaly.

The following is the average of the results obtained:

P. C. B. 100 mm. or over, many running as high as 200 mm.

Slight exophoria or orthophoria for distance and around 10° to 14° prism diopters of exophoria for near.

Prism converging power of 14 prism diopters.

Prism diverging power of 2 or 3 prism diopters.

Diplopia often found at 200 mm. from the base line.

Muscular balance normal in each eye.

Practically all of these cases had normal vision, or 20/30 vision.

All branches of the service were represented in this class with aviation the chief offender. Care was taken to ask pointed questions as to eye troubles or eye strain prior to entering the army, and invariably the answers were that they never knew what eye troubles were till they returned from the front. Considering that most of these men have previously held office positions and are now complaining greatly because of near work, it would seem conclusive evidence that this condition arose while in the service.

This brings me to the reason for writing this paper, viz.: What compensation should these men receive, and what is the best method of treatment? Basing compensation for the loss of one eye at 45 per cent., the question arises, is a man with one eye more handicapped than a man with two which cannot be used for prolonged near work? As most of these conditions are expected to improve under treatment, nevertheless during such time as he is forced to do work less exacting than his former occupation, with usually less financial remuneration, he should be allowed liberal compensation, which can be adjusted on the half-yearly plan and permanently cut off when he recovers.

Treatment is also along Dr. Duane's lines, which are practically the following: Fixing a definite point and gradually bringing the object towards the eyes until it looks double, then close the eyes and repeat many times, care being taken not to force the exercises but to slowly increase the number of times and the periods of treatment. These cases should not be permitted to do a full day's work because of the danger of fagging their convergence, and everything should be done to improve their physical condition. I might add that since starting this paper many aviators have been examined and they have complained that they cannot land

a machine from a nose dive without allowing a considerable time to get the focus, otherwise they will misjudge the distance and crash their machine.

Let me take this opportunity to thank Col. J. T. Fotheringham, D. M. S., and Professor J. M. McCallum for the opportunity of studying these cases in the military clinic at the Toronto General Hospital.

BILATERAL SUBCONJUNCTIVAL HEMORRHAGES.

Dr. Francisco M. Fernandez.

HAVANA, CUBA.

This case is a trivial one and would not have been published had it not some curious features that may make it worthy of mention.

A young man, 26 years old, consulted us, because during the first days of January, 1919, he noticed some small blood spots in his eyes.

On examination we saw very numerous hemorrhagic foci, studding both bulbar conjunctivæ the size of a millet grain, numbering from 20 to 30 in each eye. The hemorrhagic spots were also present in large numbers in both lower conjunctivae, the upper ones being free from any spots.

The history of the case was negative of any traumatism, lifting heavy weights, cough or vomiting, and the possible explanation of the cause was that the patient had been crying excessively several days previously, on account of the death of his father.

The element of surprise in this case is the possible etiologic factor, and the large number of hemorrhagic foci, as well as the occurrence in both eyes, in a symmetric formation.

SOCIETY PROCEEDINGS

ROYAL SOCIETY OF MEDICINE, SECTION OF OPHTHALMOLOGY.

March 28, 1919.

Mr. W. T. Holmes Spicer, President.

Angioid Streaks in Retina.

Mr. Elmore Brewerton exhibited a patient whose retina presented a peculiar series of angioid streaks. He brought the case because of the extensive character of the change. Tho the condition seemed to be rare, he understood Mr. Spicer had seen the appearance in more than one of his cases. On looking into the literature, he found that Ward Holden attributed such streaks to the remains of diffuse hemorrhage in a linear direction, thru the layers of the retina. But the exhibitor could not imagine blood to follow such lines, except in the nerve fibre layer, and these streaks were not in that, but posterior to it.

W. T. Lister believed the streaks to be vestiges of new vessels along whose course were arranged exudates which had undergone secondary pigmentation. The streaks in this case, however, Mr. Brewerton did not think were new vessels, as, in the left eye, they met in a lake or pool around the disc, and one could not think of a vessel extending all the way around the disc. In a case reported by Zentmayer that observer said an extravasation of blood was present while the streaks were visible. His own view was that the streaks were the remains of hemorrhage between retina and choroid. Their brown color reminded him of hematin.

The President did not think any explanation yet given of these appearances was satisfactory. He had a brother and sister with an identical condition, except that the pigmentation in those was more marked than in Mr. Brewerton's case. All four eyes of those two patients were involved in the same way. In them, it seemed im-

possible to escape the view that the lines were essentially blood vessels. Another case in which he saw the streaks was that of a very anemic man, whose condition of health was due to severe hematemesis. In the present case the streaks were not on the surface of the retina, as the retinal vessels could clearly be seen coursing over them; their position must be between retina and choroid.

Pigmentation of Cornea.

Miss Rosa Ford showed a patient with congenital pigmentation of the cornea, the pigment appearing in vertical lines.

The President mentioned cases of the kind he had seen, the pigmentation being quite deep, and the lines being, as in this case, vertical. It was not uncommon to meet with staining apart from ulceration, in which case there might not be vessels in the site.

Tumor of Pituitary Body.

Miss Ford also showed a case of what she regarded as pituitary tumor, tho she was unable to find signs of disturbance of pituitary secretion. There was, however, marked contraction of fields and left homonymous hemianopia, and a scotoma in the right field of the right eye. Skiagraphically, the sella turcica appeared to be normal.

Pulsating Tumor of Orbit.

Mr. Grimsdale exhibited a patient with a pulsating tumor of the orbit, which he regarded as aneurysmal. It appeared to be connected with the supraorbital vessels, and compression of the carotid artery on the same side caused the pulsation to cease. The patient was only 13, a very unusual time of life for such a tumor.

Macular Disease.

Mr. Rayner Batten showed a patient with disease of both macula. Three years ago she had acute papillitis, and in the course of a fortnight lost her sight completely. Three months later she could just discern light. She now had opaque white discs and symmetric disease of the macula. A feature about similar cases he had seen was that the condition occurred at about puberty. This girl had no menstruation for a year.

Intraocular Tumor.

Major Carruthers showed an intraocular growth in a soldier back from the Rhine front. When seen, the left eye was much proptosed, and X-rays showed an increased shadow on the left side. The Wassermann test proved negative. The history given by the man was one of four months—the papers had not come thru—and the first symptom noticed was diplopia. He had 4 D. of optic neuritis. The growth was quite hard. On the advice of a colleague, the man was put upon mercury and iodides, and this was soon followed by a remarkable chemosis, entirely of lymphatic nature; there was no redness, congestion, or vascular engorgement. After 48 hours this cleared up, and the proptosis and optic neuritis subsided a great deal. He was hoping it would turn out to be a gumma, and therefore curable. But the improvement stopped short of cure, and recently there had developed keratitis punctata. He believed the sinuses to be normal.

Putuitary Tumors.

Mr. A. W. Ormond showed a case of pituitary tumor. At first he thought the optic discs were involved secondarily to some nasal trouble, therefore he handed the case over to his rhinologic colleague, who explored both antra and the sphenoid, and removed the anterior end of each turbinal, but without finding anything very definite amiss. He then had the skull skiagraphed, and found the sella turcica much enlarged, so that the body of the sphenoid seemed to be eroded away. The visual fields were atypical, as the hemianopia was more on the nasal than on the temporal side. The optic neuritis on both sides, the fact that the patient was gaining flesh, and the general picture, taken with the X-ray disclosures, made him strongly suspect a malignant tumor of the pituitary body. He asked for opinions as to whether puncture should be done thru the sphe-

noid, on the chance of relieving the patient if it should prove to be a cyst.

Mr. J. H. Fisher agreed there was great probability that this was a malignant growth with very extensive destruction of the sella turcica. The absence of the typical signs of a tumor starting in the pituitary body, and the absence of the secondary phenomena which pituitary tumors manifested in other parts of the body, pointed to its malignancy. He did not advise puncture.

Mr. L. V. Cargill also showed a case of pituitary tumor, in a man aged 22, who looked 16. He had left temporal hemianopia and contraction of the right field. Both discs were pale, and there was considerable enlargement of the pituitary fossa, especially anteroposteriorly.

Mr. J. H. Fisher said this case was much more like one of primary disorder of pituitary than Mr. Ormond's. There were disturbances in the secondary sexual characteristics, and the extension in the sella turcica was of a more typical character. He still had under observation a patient, now 35 years of age, in whom the pituitary trouble had been in abeyance for 20 years. In him there was infantilism, coupled with the secondary sexual characteristics remaining undeveloped. He thought an attempt should be made to differentiate cases of disease of the pituitary body itself, and those in which the growth was in its neighborhood.

Dr. James Taylor agreed with Mr. Fisher's view. Before anything of an operative nature was undertaken, he counselled feeding the patient upon pituitary extract. If that did not succeed in giving relief, perhaps relief would be secured by operation, especially if it proved to be a cyst. Mr. Cargill replied that this patient had been fed upon the extract of the gland.

Captain Maxted read a paper on the same subject. The patient had the usual symptoms. His diplopia was preceded by intermittent headaches, not severe. The right palpebral fissure was wider than the left; the right pupil semidilated and fixed; no consensual reaction. There were attacks of epistaxis, which were attributed to a pharyngitis. He has increasing anemia. Lumbar puncture showed that the cerebrospinal fluid was under considerable tension. The fluid gave a negative Wassermann. Later the patient became dizzy. The transsphenoidal decompression greatly relieved the headaches. The right sphenoidal sinus was explored and found to be filled with a soft hemorrhagic mass, resembling growth; the posterior wall of the sinus was destroyed.

On recovering from the anesthetic, the patient noticed that his sight was much worse, and in a few hours he was practically blind. On the following morning he was completely blind, and neither pupil reacted to light. Five days later the blindness began to clear up. Ten days after the operation vision was R. 1/60, L. 4/60; six weeks after operation, R. 6/60, L. 6/24. The hemorrhagic discharge from the nose continued, the anemia progressed. A further exploration of the nose was carried out, and a vascular growth removed. A tube of radium of 100 mgs. strength was inserted, but five days after that the temperature went up, the patient became delirious, collapsed, and died. At the *post mortem* a large growth was found in the region of the sella turcica, with the optic chiasm stretched over it. There was much erosion of surrounding structures. Both cavernous sinuses were extended to three times the normal size with masses of tumor. There was great destruction of bone in the middle area of the base of the skull.

The paper was discussed by Mr. Fisher and the President.

Migrain.

Mr. J. Herbert Fisher read a paper on "Migrain." He said the primary classical symptoms of the condition were the scintillating scotomata, followed by localizing, and usually unilateral, headache; which latter culminates in nausea, or even vomiting. In his own case at least two other symptoms had been constant: A marked reduction in the pulse rate during an attack, and a definite increase in renal

activity, resulting in copious pale urine. He had never experienced one of the type-symptoms, disturbance of vision. His headache was always in the left temporofrontal position, and nausea was usual. His attacks usually lasted 48 hours. Sometimes his pulse, during attacks, was as low as 46 beats per minute. During a severe attack his alimentary activity appeared to be in abeyance.

Often in this disease there was a familial tendency. In the female the attacks often coincided with the menstrual periods, and in many cases they ceased during pregnancy, ceasing for good with the onset of the climacteric. In the male the attacks usually stopped at about the fiftieth year. The migrain spectrum usually lasted 20 to 30 minutes, as contrasted with the few seconds duration of the visual aura of epilepsy, the latter also being much more highly organized. It probably had a different explanation in the two conditions. The migrain spectrum was always symmetric, but various parts of the field might be involved. He thought the visual spectra of migrain were produced by irritation of the visual nerve fibers at the base of the brain. The hemicrania developing on the side opposite to the homonymous scintillating scotoma well agreed with the idea that the scotoma was initiated in the optic tract.

There appeared to be only one region in which a lesion, varying in character, could reach the various parts of the basal fibers, so as to explain all varieties of the migrain scotoma, namely, the interpeduncular, and he now suggested the pituitary body as the exciting agent. Slight swelling of the hypophysis would result in sufficient pressure to cause irritation of visual fibers in any of the required positions. And the cessation of migrain during gestation, when the pituitary was greatly modified, and at the climacteric, when the sex power was on the wane, all seemed to favor the view. So also did the renal activity, for the pituitary secreted a hormone which has a direct effect on renal epithelium. He had not expected to find visible changes in the region by X-rays, because there were probably no bone changes.

Dr. Gordon Holmes pointed out that Mr. Fisher's suggestion had already been put forward by another observer, the reference he would supply. He was skeptical about the theory. If it were true, one would expect to find migrainous phenomena pretty frequently in pituitary tumor cases, or in those in which that body was enlarged, either by tumor formation or physiologically. He was not aware of such phenomena occurring in those cases. His own migrinous attacks were marked by definite visual changes.

Dr. James Taylor thought the condition of the blood pressure would be a better guide to pituitary influence than pulse rate. He looked upon migrain as simply evidence of cortical irritation.

Mr. Leslie Paton described in detail the features of the migrinous attacks to which he had been subject for a number of years, an interesting point in which was the perception of an organized complex visual aura, always in the same setting.

Mr. M. S. Mayou was similarly afflicted, and his attacks were cut short by copious libations of Contrexville waters.

Mr. J. H. Parsons and Mr. J. B. Story continued the discussion

---

COLORADO OPHTHALMOLOGICAL SOCIETY

Colorado Springs

February 15, 1919.

Dr. Alexander C. Magruder, Presiding.

Tuberculosis of the Conjunctiva.

James A. Patterson, Colorado Springs, showed a case of tuberculosis of the conjunctiva in a boy of thirteen years. When the patient was first seen on September 21, 1918, the parents gave a history of enlargement of the parotid gland for some weeks, suspected to be mumps when first observed. The conjunctival trouble had been

present all the summer and had been treated by the family physician with argyrol. The upper lid of the right eye was thickened and gave the appearance of ptosis. A large tumor mass high up under the lid prevented eversion unless great force was used. The bulbar conjunctiva was free from disturbance with the exception of two small reddish elevations near the caruncle. The lower cul de sac contained another elevation, but otherwise the lower lid was free from invasion. There was also at that time great enlargement of the upper part of the parotid gland and of another gland located just below the malar process.

The patient did not appear to be ill, although his appetite was poor and his body weight below normal. He had been brought to Colorado for the relief of asthma, which had disappeared.

There were enlarged tonsils and adenoids, and on account of the difficulty in everting the lid it was decided to accomplish this under general anesthesia given for the removal of the tonsils and adenoids. At the operation on September 25th, the tarsal surface of the upper eyelid was found to be covered with large masses of granulation tissue, the majority of the granules being surmounted with suggestive pale yellow spots. Slightly to the nasal side of the center of the everted lid was a deep ulcer 3 mm. in diameter and penetrating to the cartilage. Thoro scrubbing of the tarsal surface with gauze exposed very tough edges of a linear ulcer extending horizontally along the entire tarsal surface, the ulcer already referred to being as it were the bottom of the crater. The hard edges were trimmed smooth with scissors, and cauterized with nitrat of silver. In removing the tonsils, a large mass of cheesy material was evacuated from the left supratonsillar fossa.

The diagnosis of tuberculosis, originally made from the glandular involvement and the general appearance of the eye condition, was confirmed by microscopic examination of the tissues, the sections showing characteristic areas of caseation and also tubercle bacilli. Photographs were presented showing the condition of the eyelid three weeks after the operation. The further treatment included applications of glycerit of tannin, trichloracetic acid, and formaldehyd. As there had been but slight improvement up to November 9th, on that date the use of 1/10,000 mg. of old tuberculin once a week had been begun; the dose having been first increased three weeks before the meeting, and being now 1/5,000 mg. There was a very slight local reaction after the first two injections, and after every dose of the old tuberculin there had been some lessening in size of the glandular swelling, and at the same time a barely noticeable return of the asthmatic wheeze. Of the local applications used the most beneficial had apparently been the trichloracetic acid, once weekly. There had been some extension of the process inside the lower lid.

Discussion. Melville Black, Denver, thought the general opinion seemed to be that old tuberculin was more valuable for diagnostic purposes than therapeutically; and suggested that bacillary emulsion should be used instead.

George F. Libby, Denver, recalled that in the case of ocular tuberculosis, which he had reported a few years previously, the two principal remedies employed were old tuberculin and direct rays of sunlight in gradually increasing doses. He had been inclined to think that in his case the cure was was largely produced by the old tuberculin, but thought that direct sunlight applied to the affected areas for short intervals would be beneficial in Dr. Patterson's case.

Edward Jackson, Denver, thought that this case had been very well worked out. Parinaud's disease had apparently been thoroly excluded by the pathologic findings.

Radiating Lens Opacities.

E. R. Neeper, Colorado Springs, presented a woman aged 40 years whose eyes had been refracted in 1906, when corrected vision of 20/20ths was obtained in each eye; and again in December, 1917, when the corrected vi-

sion obtained was only, Right 20/50ths plus, and Left 20/30ths, and multiple slight opacities were noticed in each lens. At the present time the corrected vision was approximately the same as in 1917. The opacities were ten or twelve in number, extremely delicate, lying peripherally in about the middle plane of the lens. Dionin had been used for about one year.

Discussion. Edward Jackson, Denver. The arrangement of these opacities is the same as in so-called blue cataract, being outside the undilated pupil, and much better seen by oblique illumination than with the ophthalmoscope, with which they appear rather as refractive differences in the lens, and the whole having a bluish appearance. It would be well to examine this case by ordinary daylight, with the pupil dilated. Even if the case is not exactly what is known as blue cataract, it is probably of that general character; and the prognosis may be relatively good, in that the condition may advance very slowly.

Dr. Neeper said the opacities were very noticeable with the ophthalmoscope.

Melville Black, Denver, suggested that in these cases of opacity of the lens in relatively young people it was necessary to assume disturbance of nutrition of the lens through the ciliary body, which might be due to focal infection. The patient had a large number of filled teeth and one tooth broken off. It would be well to radiograph for the possibility of dead teeth.

Cataract with Doubtful Light Projection.

E. R. Neeper, Colorado Springs, presented a woman aged 66 years for opinion as to the advisability of extracting a dense cataract from the left eye in view of the fact that this eye was uncertain as to light projection. The vision of the other eye was 20/50ths.

Discussion. Edward Jackson, Denver. It is possible to have a cataract which cuts off light projection completely and yet get good results. This patient apparently perceives the light wherever it is held. Light projection is relatively best in the slowly forming nuclear cataracts, but in a white cataract of this kind the light diffused from the lens probably drowns out the image of a point of light in the fundus. The reaction of the pupil being excellent gives a good prognosis in this case.

Several other speakers regarded the prognosis as good.

Cataract Extraction, Poor Vision Unexplained.

E. R. Neeper, Colorado Springs, presented a woman of 67 years upon whose left eye cataract extraction had been done with apparent success, but with unexplained failure to obtain vision. The vision of this eye in January, 1917, was 16/200ths. Light projection was normal. In April, 1918, the vision of the eye was of movements. The atropin used in connection with a successful preliminary iridectomy produced a great deal of irritation. In August, 1918, cataract extraction was done under local anesthesia, and hysocin and morphin hypodermically, no difficulty being encountered. During the first few dressings the patient spoke of good visual results, but the vision soon began to fail and a month later the eye was blind. Later it was discovered that there was slight light perception in the lower temporal quadrant. Transillumination of the eye was normal, but the retina was indistinctly visible, although there was only a very slight capsular opacity. In view of the fact that the vision of the second eye was almost gone, it was important to consider what was responsible for the loss of vision in the eye which had been operated upon. Further, would it be advisable, in operating upon the second eye, to use atropin subconjunctivally?

Discussion. C. E. Walker, Denver, and several other speakers were in favor of needling the capsule, altho recognizing that the opacity here did not explain the visual condition.

D. A. Strickler, Denver, suggested that the more frequent use of hyoscin and morphin in nervous cases of cata-

ract extraction was advisable, such patients being very quiet under this treatment.

George F. Libby, Denver, and W. H. Crisp, Denver, were disposed to think that the retina was detached.

Melville Black, Denver, believed that a broad iridectomy done on the second eye some time before extraction was undertaken would avoid the necessity for atropin.

Edward Jackson, Denver, did not consider it advisable to try subconjunctival injection of atropin. He thought that the extraction could be done on the second eye either with or without iridectomy.

W. C. Bane, Denver, would try the use of salt injections subconjunctivally and of iodides internally, on the basis of the possibility of detachment being present.

Penetrating Injuries.

E. R. Neeper, Colorado Springs, presented a man aged 33 years who on September 13th, 1918, had received a number of injuries from gunshot and particles of brick. The left eye had been destroyed and was enucleated on October 29th. The most important wounds of the right eye were one passing through the lower lid, probably grazing the eyeball on the lower side and entering the sphenoid, and another entering the bulbar conjunctiva 4 mm. to the temporal side of the limbus and also passing into the sphenoid. This latter injury did not puncture the sclera, altho the course of the foreign body was indicated by an anteroposterior line of hemorrhage within the vitreous. The remains of this hemorrhage greatly disturbed the vision of this eye; but the exudate was gradually diminishing, and when the eye was kept still vision of 20/50ths was obtained. There was much retinal edema at first, but this had disappeared. There was marked drainage thru the nose from the posterior orbital cavity or from the nasal sinuses. An x-ray report was to the effect that there were fragments three-quarters of an inch behind the eyeball, probably in the sphenoid.

Dr. Neeper also presented a man aged 26 years whose left eyeball had been injured on June 27, 1918, by the explosion of a water glass on a stationary engine. A piece of glass had cut through the left lower lid, laying it wide open and then through the eyeball, making a 7 mm. vertical incision through the nasal side below the limbus, and had left the eyeball at and below the temporal portion of the disc. Both the eyelid and the anterior wound in the eyeball were stitched. The wound of exit was clearly visible, and there was also a ribbon-shaped exudate which hung vertically in the anterior vitreous to the nasal side. Three days after the injury a vertical line 1 mm. wide, and having a gelatinous appearance, showed on the anterior capsule of the lens. This disappeared after several days. Except for a slight hemorrhage into the vitreous at the point of exit, the media generally had been quite transparent all the time. The vision of this eye, which on July 25th was 20/200ths, was now 20/40ths with or without correction.

Dr. Neeper further presented a man aged 36 years, who on April 19, 1918, had received in the right eye a lacerated wound about 14 mm. long. The wound, which was in the general neighborhood of the upper nasal limbus, included the cornea, iris, lens, conjunctiva, and sclera, and the upper lid near the punctum also showed a 4 mm. wound. The vitreous and iris which projected were clipped off and the wounds were stitched. There was comparatively slight reaction and healing was prompt. The irregular pupil was filled with opaque lens matter in the capsule, but this was clearing gradually. Should dionin and atropin be continued? Should the lens matter be removed? Should the eye be enucleated?

Discussion. W. C. Bane, Denver, as regards the last case, would leave the eye alone, in view of the excellent results.

C. E. Walker, Denver, would be inclined to extract the lens. He was surprised, as regards the case of vitreous prolapse shown by Dr. Neeper, and

also as regards cases previously seen with other members of the society, at the excellent results obtained without operative interference with prolapsed vitreous, and by the use of little or no pressure.

W. H. Crisp, Denver, said that this eye would not be made worse by operating, and that it would be well to get the milky lens out of the way.

D. A. Strickler, Denver, had seen an interesting case, in which an eye which had been cut by being thrown against a wind shield, with a resulting large open wound in the sclera. The eye had healed with vision of 20/30ths after practically open treatment with very little pressure.

Dr. Neeper said that it did not seem right to him to leave intraocular tissue strangulated and protruding from the eye, when it could be cut off with scissors.

Dr. Walker remarked that in the cases to which he had referred nothing had been cut off, and no infection had resulted, the protruding part apparently receding into the eyeball.

Obscure Ocular Infection in Infancy.

F. E. Wallace, Pueblo, reported a case of severe ocular infection in a baby between the ages of two and six months. At two months of age the preauricular and submaxillary glands of the right side were enlarged, and a few days later a moderate purulent discharge began from the right eye. The amount of pus increased gradually, and the upper lid became swollen and the eyeball red. About two months later the right ear began to discharge. The patient was under the care of a general physician who did not examine the eye. Dr. Wallace first saw the case on January 22, 1919. The moderately swollen upper lid overrode the lower 5 or 6 mm. There was slight mucopurulent discharge, the preauricular glands were moderately and the submaxillary glands more greatly enlarged. The inner half of the tarsal surface of the upper lid was covered with a dirty yellowish membrane, and there were two smaller but similar areas toward the outer end of the tarsal surface. The membrane, which was not elevated above the general surface, was very hard to loosen and bled freely. The retrotarsal fold was board-like in consistency, and a dirty white in color. The conjunctiva of the lower lid was affected similarly but to a less degree. The bulbar conjunctiva was edematous, was of purplish red color, and had an elevation of about 2 mm. next to the limbus. The cornea was almost uniformly cloudy, and the details of the iris could not be made out. A culture made from some of the tissues was negative for diphtheria, and examination of the pus showed only the ordinary pus organisms. Under treatment the lids improved but the cornea gradually broke down. The case was lost sight of.

Discussion. C. E. Walker, Denver, thought that the infection was likely to have come originally from the orbital tissue, and might perhaps have burrowed thru the sphenoidal fissure.

Iritis from Antrum Infection.

A. C. Magruder, Colorado Springs, presented a woman in whom bilateral iritis had been due to an infection in the left antrum. The case was first seen on January 14, 1919, when the conjunctiva of each eye was intensely congested, and there was severe pain with photophobia. The irides were sluggish and the pupils were small. The condition had lasted two or three weeks. There was pain on pressure over the left frontal sinus and over the left antrum. The antrum was washed out thru the nose and only boric acid solution was used in the eyes. The next day there was improvement in both eyes and in one week the patient was discharged, the antrum having been washed out four times. The infection was with pneumococcus and staphylococcus.

Discussion. W. C. Bane, Denver, mentioned a case of destructive ulcer of the cornea as the result of which the eye was lost. During treatment of the eye it was discovered that the corresponding antrum contained pus. For some days after washing out the antrum there was marked improvement

in the eye, but the iris was so bound down that it was impossible to get satisfactory drainage within the eye.

Syphilitic Optic Atrophy.

A. C. Magruder, Colorado Springs, presented a man of 37 years who, on January 4, 1917, had come with vision in either eye of 1/10. There was atrophy in the temporal side of each optic disc. Under potassium iodid and mercurial ointment the vision improved in three weeks to 4/10 in each eye. The patient had not been seen again until February 13, 1919, when the vision in each eye was 3/10. There had been no treatment for eighteen months.

W. H. Crisp, Secretary.

SECTION ON OPHTHALMOLOGY, COLLEGE OF PHYSICIANS OF PHILADELPHIA

January 16, 1919.

Dr. William T. Shoemaker, Chairman.

Spontaneous Rupture of the Anterior Lens Capsule with Rapid Development of Cataract.

Dr. William Zentmayer exhibited a case unique in his experience. A cataract due to a break in the anterior capsule of the lens revealed by the dilatation of the pupil in an eye with an apparently perforating corneal ulcer occasioned surprise which turned to astonishment on the later occurrence of a similar condition of the lens and its capsule in the fellow eye showing no recent signs of trauma or inflammation. O. M., female, aged 19 years, came to the Wills Hospital October 9, 1918. She was employed in weighing powder in a munitions plant. The left eye had been sore for ten days. There was no history of trauma. She was an epileptic. There was moderate photophobia and lacrimation with marked ciliary congestion. The cornea was hazy thruout and showed a perforated ulcer in its lower inner sector corresponding to the position of the pupillary border of the iris. The iris was engaged in the ulcer and the pupillary area was opaque. This was at the time supposed to be due to exudation. Later, however, when the pupil had been dilated with atropin it was determined to be opaque lens-matter protruding from a rent in the anterior capsule. V. = L. P. In the right eye the cornea showed fine linear and curvilinear gray opacities in its lower and also temporal portion. On the temporal side there was an absence of complete differentiation between the corneal and scleral tissue and there was what appeared to be a small congenital symblepharon. Fundus normal. V. = 6/12.

She was admitted to the hospital, an X-ray was made and appeared negative. Under appropriate treatment the inflammation subsided and when she was discharged on October 21 the globe was white and the anterior chamber shallow, pupil nearly round, there being a slight anterior synechia. The lens was opaque and cortical protruded from the rent in the anterior capsule. V. = hand movements.

After her discharge she was seen a few times in the dispensary for treatment of the affected eye, and on October 25 she again reported, stating that two days previously on arising in the morning she was unable to see to go to work. Vision gradually grew worse. There was very slight ciliary injection; the cornea showed the condition previously noted and the lens was cataractous, cortical matter protruding into the anterior chamber. V. = hand movements. On December 4 a linear extraction was done on the right eye, and on December 16 a needling of the remaining cortical and capsule. January 13: V. = 20/100 + 13 D.

Two possible explanations of the condition present themselves: (1) Tetany and (2) selfinduced trauma. Tetany is a well-recognized cause or accompaniment of cataract. A history of convulsions is present in a not inconsiderable percentage of zonular cataract and there are observers who claim to have found tetany a cause or accompaniment in many cases of senile cataract. It is possible that the associated conditions in the first instance have a common cause in a disturbance

of metabolism arising from abnormalities in the secretion of one or more of the endocrine organs. Whether repeated convulsions could cause a rupture of the capsule in a normal development is doubtful when we consider the frequency of epilepsy and the absence so far as Dr. Zentmayer knew of any previously reported cases of cataract arising in this way. It is conceivable that there may have been a structural weakness of the capsule thru faulty development. The theory of self induction in this case would have had stronger support if the cataract had been combined with a corneal lesion in the second eye. But in this eye there was no evidence of a recent wound or ulcer of the cornea. When the patient presented herself, two days after the loss of vision had been noted, the anterior chamber was shallow and the eye was slightly injected, both symptoms were probably due to the swollen lens.

Dr. Ziegler stated that the three prominent factors to be studied in Dr. Zentmayer's case of ruptured capsule were chemical erosion, ulceration and trauma from the convulsive seizure. Undoubtedly the chemistry of metabolism in an epileptic was always perverted, but whether this could extend to the lens substance was difficult to demonstrate. He had seen a case of exceedingly irritating chemicals in a lens cortex that produced an exacerbation of glaucoma whenever the capsular contents escaped. Ulceration could only be considered by analogy as the history shows such a lesion on one cornea just over the ruptured capsule. Weakening of the capsule, either by erosion or ulceration would undoubtedly encourage traumatic rupture in a case of epileptiform convulsion, but the exact lesion of the capsule could only be determined by withdrawing the ruptured capsule for microscopic examination. This might prove difficult to accomplish.

Dr. Zentmayer, closing the discussion, said the case was seen by Dr. Lucien Howe while he was in Philadelphia and he suggested that it was probably due to injury self induced. Colonel Parker suggested an abnormality in the capsule and thought that possibly rupture of the capsule might have resulted from the falls when the patient was in convulsion.

Extensive Pigment Changes in the Retina Following Injury.

Dr. Krauss presented a case of a boy who was struck by a B. B. shot in the left eye. The X-ray two days later showed the ball very plainly in the anterior part of the orbit. Later X-ray plates showed the disappearance of the ball. As no ball could be found, Dr. Krauss thought that the apparent shot in the eye was made by the staining of the tissues by the lead ball. The retinal changes were very marked in the pigment layers, resulting in many pinhead opacities scattered thru the lower half of the eyeball with a large mass to the temporal side.

Dr. C. R. Heed, in discussing the X-ray plates exhibited by Dr. Krauss, directed attention to the symmetric shadows of the anteroposterior and the lateral exposures, indicating that the body casting the shadow must have been spheroidal in shape. Krauss's explanation that the shadows were made by a filmlike deposit on the eyelids does not bear out the shadows on the plates. It is hardly possible that a film of lead on the lids would be shown on the plates after the rays had passed thru the head, but if we concede that such is a possibility the anteroposterior shadow would be circular while the lateral one would be not much more than a line or a narrow ovoid streak.

Burton Chance called attention to the marked pigmentary changes at the posterior pole of the affected eye in Dr. Krauss's case. Changes such as are there presented have been recorded but seldom in recent years. He was sure that the Chairman, Dr. Shoemaker, had seen, alas, too many cases, while it has been his own privilege to have had under observation 30 cases following direct injury to the globe. And he is certain that similar cases will arise frequently in our practice now that the wounded are being returned. It will be interesting to observe the progress

of Dr. Krauss's case and to note whether in the course of time the pigment masses shall disappear only to reveal irreparable lesions of the choroid.

Dr. Ziegler asked Dr. Krauss whether the crescentic ulcers on the lid margins might not be due to friction burns. If a B. B. shot should spin around after striking the tissues it might produce a burn from friction and also make a deposit of lead that would obstruct the passage of the X-rays in at least one direction. Experiment might determine these points.

Disseminated Unilateral Choroiditis.

Dr. Krauss also reported a case of unilateral disseminated choroiditis, occurring in a seventeen-year-old boy. The lesions varied from a slight yellowish fluffy swelling of the choroid to a more advanced aggregation and absorption of pigment. There were no vitreous opacities. Wassermann, + 1.

Dr. Risley said the ophthalmoscopic picture reminded him of the conditions he had seen follow the intravenous injections of salvarsan in a patient with syphilis, who had been under his observation prior to the injection. The occurrence of ocular disease following these injections had been so frequently observed that he regarded it as a serious menace in the use of salvarsan.

Adventitious Hyaloid Membrane.

Dr. S. Lewis Ziegler again called attention to the adventitious hyaloid membrane which he thought was forming in the case of V-shaped iridotomy exhibited by him last month. Such a hyaloid membrane is liable to form in any case of aphakia where an incision of the iris or capsule exposes the vitreous body to the action of the aqueous. As a matter of fact, it seldom occurs. Dr. Ziegler had only observed it in some six or eight cases during a period of more than thirty years.

The two characteristic symptoms are: (1) A faint opalescent reflex of the vitreous surface when exposed to oblique illumination; and (2) inability to correct the near vision beyond J-10 or 12, altho the distant vision may have been corrected up to 20/30. Such a result, of course, does not yield useful reading vision and is a source of annoyance to both patient and physician. In other words, there is a distinct lack of normal proportion between the distant and near vision in an aphakic eye that may otherwise appear to be perfectly normal.

The proper procedure in such a case, altho no capsular membrane is visible, is to make a *pro forma* incision of the vitreous surface exposed in the pupillary area (V-shaped or otherwise), just as tho the original capsule was still *in situ*. In practically every case of this type that Dr. Ziegler had operated on good reading vision (J-1 to 4), had been obtained by this procedure.

In the case of iridotomy shown last month it will be recalled that the distant vision with correcting lens was 20/70 and the vision for near J-12. The hyaloid film was incised on December 28, 1918, and one week later the same glasses yielded a vision of 20/30 and J-1. That this intangible film was really a tangible membrane was further demonstrated by a distinct sensation of iridic retraction and widening of the pupil at the very moment that the film was incised.

Dr. Krauss stated that he had seen similar cases occurring usually after the extraction of the brown or sclerosed type of lens. The healing in these cases is usually quiet with no capsule remaining. The vision is reduced, tho a splendid view of the eyeground is obtained. Dr. Krauss believes that this fine opacity which is seen only by indirect illumination is due to a wrinkling in the anterior limiting membrane of the vitreous. A very free needling thru the pupillary area gives a good result, altho no membrane can be seen to needle.

Dr. S. D. Risley, discussing Dr. Ziegler's case, said that he had several times been disappointed because of the low acuity of vision after successful extractions of cataract leaving an apparently clear black pupil and good but a slightly blurred ophthalmoscopic view of the fundus, and revealing no serious pathologic change in the uvea

or lack of consistency in the vitreous. In using the plane retinoscopic mirror, however, he discovered, when the light from the mirror fell obliquely upon the pupil, a finely striated, iridescent faint sheen back of the pupil, reminding one of the colored sheen seen on the interior of a clam or oyster shell. He had ascribed this appearance to a disturbance of what the anatomist would call the "anterior limiting membrane" of the vitreous body. With this explanation in mind he had not ventured upon any operative interference.

J. Milton Griscom, M. D.,
Clerk.

CHICAGO OPHTHALMOLOGICAL SOCIETY.

FEBRUARY 17, 1919

PRESIDENT, DR. WILLIAM L. NOBLE IN THE CHAIR.

Fundus Pathology With the Red-Free Light of Vogt.

Dr. Robert von der Heydt read the paper on this subject published in full in this journal, p. 334.

Discussion.—Dr. Michael Goldenburg said he became so interested in this lamp when Dr. Von der Heydt first called attention to it that he asked him to loan it to him and spent an entire afternoon looking at cases of various kinds. The lamp at present was not perfect, but he felt that Dr. von der Heydt should be given a great deal of credit for his work so far. The light offered wonderful avenues of approach which had never been available before. He had examined a number of cases; and in one that he thought was an embolism of the central retinal artery with hemorrhages, the free blood looked black.

The vascularization upon the disc of very fine vessels, which was not seen with the ordinary illumination was visible as little black lines running across a white field. We were not sure about the nerve fibers, but thought we could see them in one case. It required a good deal of practice to judge these things, and the three who had seen the case did not think they had sufficient experience to decide. In one case with an apparently normal fundus he had never been able to see the so-called choroidal opacities before, but saw numbers of them when using this light.

Probably the most fascinating part of the red-free light was the ability to see the macula, as bright canary yellow, just like a bright brilliant spot in the blue field. They examined one case that was going through a low-grade form of neuro-retinitis. The patient had had several attacks. He did not feel that he could see the yellow in the macula in that case and neither did Dr. Crossley, but they could see it in the others, of what significance, this might be he did not know.

In the patient he had presented to the Society, where there were fine fibers out to the nasal side, one could see the white lines very thin but visible, and the hemorrhages were apparent, standing out as black spots. He could trace the fibers from the disc out for a way, but not to the macula. but this was probably because he was not familiar with the use of the instrument.

Unquestionably the red-free light would be of unlimited value in the early diagnosis of retinal and optic nerve conditions. In the case of a colored woman examined, he thought his glass had black spots, for in looking at the fundus the ordinary tesselated picture appeared, as definite black and white stripes—a very marked contrast. He had never seen a similar picture.

Dr. E. R. Crossley stated that he had had the pleasure of examining the cases with Dr. Goldenburg and the macula stood out very well. In one comparatively normal case one could see the nerve fibers coming out but could not trace them around the macula as was described. On more experience with the light one might be able to do so. The blood vessels stood out plain and black and it gave a very good view of the macula.

Dr. von der Heydt, in closing, said that Vogt and Affolter had been using

the light since 1913 and had a vast amount of literature on the subject. Last fall he had the filters made and showed them to the Society. With ordinary light it was comparatively simple to use the ophthalmoscope. One could pick up the light anywhere. With the red-free light, however, one had to seek the center of the cone of light. If one got into the periphery one ran into chromatic aberration.

His instrument was so tilted that it threw the cone of light in an upward incline. This enabled him to seat the patient at varying distances, according to his height. He guided himself by the bluish disc, thrown on the window shade, watched the image of the patient's head in it and led his ophthalmoscopic mirror into the center of the cone of light. The colored person, rich in pigment was comparatively a poor subject for the red-free light.

In the embolism case, seen with Dr. Goldenburg, he could not expect to see much more with the red-free light than with ordinary light, because the case was a very recent one. There was still an edema of the retina and it was too early to expect to see the atrophic zones which would later be visible in the fiber layer of the retina.

Orbital Abscesses.

Dr. Robert H. Good read a paper on this subject in which he considered orbital abscesses caused by infections of the anatomic structures adjacent to the orbit, with special reference to the early manifestations of intracranial complications, so that by early operative procedure many cases might be arrested before developing meningitis and brain abscess. These abscesses were either subperiosteal, between periosteum and orbital bony wall, or between the extrinsic muscles with their membranous connections, and the periosteum; or between the extrinsic muscles and the optic nerve in the orbital fat.

Etiology.—1. Subperiosteal abscesses in the orbit were by far the most frequent and were caused by acute and chronic inflammations of the ethmoid, frontal sinus, maxillary sinus and sphenoid sinus. A good stereo-X-ray would show whether the orbital wall was necrosed or not. Fractures of the orbit might cause a subperiosteal hemorrhage, which, if it became infected, formed an abscess. Extradural abscesses might find their way from the anterior fossa of the skull thru the optic foramen external to the orbital periosteum. However, it was more frequent to have the pus go in the other direction, causing an extradural abscess from the orbital abscess. Tumors in the nose, such as polypi, fibroma and sarcoma, were often the cause of this form of orbital abscess. Tuberculosis and syphilis of the orbital bony wall were common.

2. Abscess between the periosteum and the extrinsic muscles of the eye, with their membranous connective sheath, were caused by an extraperiosteal abscess breaking through the periosteum into this space. Trauma, such as blows, causing hemorrhages in the subcutaneous areolar tissue would form an abscess in this space if the blood clot became infected. Penetrating wounds and foreign bodies along the margin of the orbit, external to the extrinsic muscles of the eye and internal to the periosteum, would cause the abscess to form in this space. In dacryocystitis the sac might rupture into this region. Infection from subconjunctival injections of the eye would form an abscess in this space. Abscess of the lacrimal gland might rupture into this space.

3. Abscesses internal to the extrinsic muscles were in the orbital fat around the optic nerve. As the membranous connective tissue sheath between the extrinsic muscles was very thin, it did not form a great barrier to the abscess external to the extrinsic muscles from breaking into this region. Ulcers of the cornea, panophthalmitis and penetrating wounds of the sclera had caused abscesses in this area of orbital fat. Penetrating wounds and foreign bodies posterior to the bulb and thru the extrinsic muscles, or surgical procedures which entered this space, followed by infection, were sometimes etiologic factors. The

sphenoidal sinus was more frequently responsible for an abscess in the orbital fat than the other sinuses. The serious complications were extradural abscess, optic neuritis, optic atrophy, meningitis, brain abscess and thrombosis of the cavernous sinus.

The extradural space was continuous with the subperiosteal space of the orbit and communicated with each other through the optic foramen, so that a subperiosteal orbital abscess might drain into the extradural space and form an extradural abscess. The optic nerve had the same coverings as the brain, namely, from without in, the inner layer of the dura, arachnoid and the pia. The subdural lymph space in the skull extended all along the optic nerve to the eyeball and the subarachnoid space, which contained the cerebrospinal fluid, and communicated with the subarachnoid space of the optic nerve.

The dura of the optic nerve was only the inner layer of the dura, and was thin compared with the dura of the skull, and it was very vascular with many blood vessels entering it, so that toxins would penetrate it much more readily than the dura of the skull. The dura of the optic nerve differed from the skull dura, in that it did not have the properties of forming bone, and, therefore, was much less dense in structure.

When toxins entered the subdural space of the nerve, they might cause cerebral symptoms, and if they entered the subarachnoid space of the nerve, they resulted in cerebrospinal meningitis because this space was in direct communication with the cerebrospinal fluid. An abscess pressing on the nerve with accompanying edema, as well as absorption of toxins, resulted in optic neuritis and atrophy. An abscess around the optic nerve in the orbital fat pushed the eye straight forward and generally ended in blindness or in meningitis. Involvement of the central vein of the retina or the ophthalmic vein resulted in thrombosis which might extend to the cavernous sinus and produce the same symptoms as lateral sinus thrombosis.

The most frequent location of the abscess was at the inner anterior aspect of the orbit in the region of the lamina papyracea of the ethmoid cells which causes the eye to be pushed outward and somewhat downward.

The next frequent location was in the upper and inner angle of the orbit where the frontal sinus wall was the thinnest, and pushed the eye downward and outward. Either of these, if untreated, might break and leave a fistula above the inner canthus of the eye. When due to maxillary sinus infection, the abscess was in the floor of the orbit and pushed the eye up and outward. Orbital abscess from the posterior ethmoid and sphenoidal sinus were rare, but when they did occur the eye was pushed forward and the pain was severe even in chronic cases.

The symptoms varied greatly, depending upon whether it was acute or chronic, the part and extent of the orbit involved, as well as the nature of the infection. In chronic cases the symptoms were usually mild, a slight pain with tenderness on pressure. There was slight swelling of the lids and conjunctiva. On palpation a firm mass could be felt. The febrile symptoms were usually negative. In acute cases we had a different picture, especially if the abscess were between the periosteum and the extrinsic muscles or in the adipose tissue. There was marked exophthalmos and great swelling of the lids and conjunctiva with inability to close the eye. The pain was severe in the orbit, radiating to the temple. The temperature was usually high, from 100° to 103° F. with a correspondingly rapid pulse. The eyeball was almost immovable and the power of accommodation was lost.

When the abscess burrowed along the periosteum or along the dura of the optic nerve, it entered the extradural space of the skull by way of the optic foramen and produced an extradural abscess which caused an absolute change in symptoms and could easily be diagnosed. The swelling might slightly diminish but the pain was greatly increased and deep seated in the forehead. The tenderness in the

eye might be the same or lessened, but when the skull was firmly compressed over the painful area, the pain was much more marked. The temperature dropped to 96° or 97° no matter if the temperature had been 104°. The temperature lingered around subnormal to 99°. The pulse dropped at times as low as 50. In addition the patient complained of dizziness, especially on stooping. The projectile or cerebral vomiting was always present, and the mental symptoms varied from indifference and slow cerebration to coma. The blood pressure was increased.

In these cases, in addition to opening the abscess one must expose the dura by removing the posterior wall of the frontal sinus and the patient would make an uneventful rapid recovery.

When the toxins entered into the subdural space, the symptoms were those of mild cerebral irritation; whereas, if they entered into the subarachnoid space of the optic nerve, it caused a cerebrospinal meningitis; both of which should be treated with Flexner's or Lederle's antimeningitis serum intraspinally.

As to treatment, an incision was made through the skin over the most prominent portion of the abscess, not necessarily into the abscess, then a small curved blunt artery forceps was inserted into the abscess and withdrawn by opening the forceps. Care should be taken to direct the forceps towards the orbital wall, instead of the optic nerve region, so as not to penetrate the extrinsic muscles or their membranous sheath, as most abscesses were external to these. When the abscess was very large and surrounded the bulb, it was wise to drain it in more than one place.

The great majority of orbital abscesses were due to sinus infections, and in these cases the sinuses should be thoroly drained in addition to the above. Where the abscess was outside of the orbital periosteum and the sinus wall was broken down, an intranasal operation on any of the sinuses was insufficient to relieve the orbital abscess. Ten years ago the speaker was of the opinion that the frontal sinus or ethmoids had to be opened from the outside. But his experience in intranasal sinus surgery had proved to him that these cases recovered faster with less tendency to recurrence with the intranasal than the external operations.

Discussion.—Dr. Oliver Tydings complimented Dr. Good on the work and illustrations he had presented. He said he had a case under his care at present who was operated upon by a man who was an expert, but the patient was blind in one eye. The history was unique. The patient had some intense pain which the speaker attributed to an eye trouble, an infective condition. Blindness was due to orbital pressure. She never had any pus but had sinus pain; and the sinus was opened on the left side and following that was a mastoiditis. That was operated upon and from what the patient said there must have been a meningitis which lasted for some days, during which time she claimed to have been unconscious. The patient finally recovered from that but still had a suppurating condition. He did a radical mastoid but had not yet finished the nasal work. The operations described by Dr. Good were apparently safe in his hands but, unfortunately, were not always safe in the hands of some others.

In the treatment of these cases he had followed practically in the line laid down by Dr. Good, except in infants. An orbital abscess due to a sinus condition he thought would not be very safe. He had treated most of those cases and he felt that the fact that he knew so much about nose work might account somewhat for the success he had in treating them. He would make both an external and internal incision, starting down through the projecting portion and making an incision through the orbital plate of the ethmoid and down through the nose, a single incision, usually breaking the abscess down with the knife, being careful not to cut any muscular tissue. He had operated quite a large number of cases in that way, in children perhaps less than two years old,

with very good results. He felt that free drainage was worth a great deal in these cases.

Dr. H. H. Lebensohn thought that an orbital abscess was just like one any place else. It made no difference originally where the infection came from, as to what sort of an infection it was. About four years ago a man of seventy developed a large orbital abscess following probing of a stenosis of the lacrimal duct. Within twenty-four hours after the probing he developed an orbital abscess and they found a pure streptococcus culture. It was opened several times, no pus was found, but it finally got to the eye. The same night he had another case and that was a staphylococcus infection. It was opened and drained and within a week or ten days the patient got well.

In a patient who had recently been discharged, a boy of eighteen, he could not make a diagnosis as to the etiology. It looked like an ethmoid infection with an almost pure pneumococci culture. He drained the abscess and when it was opened he got between three and four drams of pus. He kept on ethyl hydrochlorat with little strips of gauze and it cleared up remarkably well. He thought it was not so much the opening, but advised opening them as soon as possible. He thought the prognosis would depend upon what the infection was. The staphylococci infections have a good prognosis, the pneumococci and streptococci bad.

Dr. R. H. Good, in closing, agreed with Dr. Tydings that establishing a perfect drainage was the best treatment.

In cases of suspected ethmoid infection instead of spending so much time in finding out the nature of the infection bacteriologically, it was a better plan to take a stereoroentgenogram and find out the nature of the condition at once.

Embolism of Central Retinal Artery as a Complication of Influenza.

Dr. Michael Goldenburg exhibited a case of this kind. Mrs. E., aet. 22, married, one child. Had always been in good health On November 20th, 1918, during the virulent epidemic of influenza, she developed this disease, passing through the usual stages, a very sick individual. On about the eighth day, when her temperature was at its highest point, she suddenly felt something had happened to her right eye; then noted that she was blind in that eye; and further states that the eye felt stiff and was wild looking; and later the eye deviated outward. I should judge from her description that the pupil was widely dilated.

On February 12, 1919, she presented herself to our clinic at "The Illinois Charitable Eye and Ear Infirmary."

Examination: Lids, conjunctiva, cornea and anterior chamber negative. Pupils equal and react to light. Vision, Right: Fingers at two feet and then only in the upper temporal field. Left: 20/20-3.

Fundus, Right: Disc primary optic atrophy, cloudy grayish pink area about two disc diameters noted from disc temporalward beyond macular region. All arteries markedly diminished in calibre, except upper temporal branch which is about half the normal in diameter. Branches running nasalward very thin and end in white lines. Many small hemorrhages in region of macula and on nasal side both superficial and deep. Directly over bifurcation of artery a small grayish dot is noted that I was inclined to think was in the vessel, but could not be positive; other observers would make no definite statement upon that fact.

Left: fundus and media negative.

General physical examination, made by a competent internist disclosed the following: Heart negative. Aortic second sound slightly accentuated, which speaks against a valvular lesion. Lungs: not quite healed. In right upper part of lung still some consolidation that could be tubercular, but most likely an unresolved area. Blood pressure: 120. Urine: Negative.

ABSTRACTS

Fromaget, C. and H. Functional Anisocoria. Archives d'Ophtalmologie, v. 36, p. 277.

Functional anisocoria is a clinical syndrome without organic lesion, due to an instability of the supranuclear center which coordinates the pupillary movements. This definition is analogous to that obtaining for functional strabismus or nystagmus, and it was the study of these latter two that led the authors to study the former and to seek an explanation for the many cases of anisocoria of obscure origin which presented no organic, ocular, nervous, cervical, mediastinal, or other lesion, with preservation of the essential iridic functions.

Observation 1. C——, aged 30, was subjected, on account of his unsatisfactory conduct while under fire, to a medicolegal examination, which, altho thoro and extending over a fortnight, revealed nothing. There was no strabismus, either manifest or latent, and the pupils were equal, regular, and responded to all stimuli. Vision of R. and L. = 6/6, no correction accepted. He was, therefore, notified that he was to be returned to the front. Twelve hours later he complained of blurred vision; his vision was still normal, but a mild transient, alternating strabismus was noticed. Pupils were equal and reacted normally. On the following day the strabismus was more pronounced, and transient inequality of the pupils appeared. Two days later the strabismus was confined to the right eye, and when the object fixed was five meters distant the secondary deviation was equal to the primary, 15°; whereas at 20 centimeters distance, no strabismus could be demonstrated. At the same time the inequality of the pupils became very evident, the right pupil measuring 5 mm., and the left pupil 3.5 mm. in ordinary light, with the eyes fixed on an object in middle distance. The pupils still react well to direct and indirect illumination, but feebly on convergence. Cocain dilates both pupils without causing them to become quite equal. The subjective symptoms are not marked; the patient reads with ease and finds his way about the room without hesitation. Bandaging the right eye for twenty-four hours brought about a complete disappearance of the anisocoria and a marked diminution of the strabismus, but the pupils still remained immobile on convergence. A short time after the removal of the bandage the anisocoria reappeared and the strabismus increased. Bandaging the left eye for forty-eight hours gave the same result. Instillation of atropin for three days caused a still greater diminution of the convergence and elicited a hypermetropia of 1. 5 D. When the effect of atropin had worn off a small amount of strabismus remained, and the refraction again simulated emmetropia; a feeble reaction of the pupils on convergence was present.

Again the nervous system was gone over without yielding any diagnostic point. The spinal fluid was clear, the Wassermann reaction of the spinal fluid and of the blood was negative. Radiographic examination of neck and mediastinum were also negative. A psychiatric examination gave the following: Emotional psycho-neurosis, with psychic, senso-motor sensitive-motor, and splanchnic manifestations. The patient was placed on sedative treatment, both mental and physical, with complete disappearance of all his symptoms, after being under observation for a period of three months. He had been assured that his trouble would disappear completely, and his physical improvement kept pace with his mental amelioration.

The authors call attention to the parallelism existing between functional anisocoria and functional strabismus. This functional inequality of the pupils develops in eyes in which the intrinsic motor apparatus is intact and the iridic functions normal. It arises and persists under the domination of the same occasional factors as functional strabismus. The question arises, are these

phenomena manifestations of hysteria, or, to employ a better term, of pithiatism (*pithiatism*—a state of mind which renders the patient subject to persuasion; a term proposed by Babinski as an equivalent of hysteria)? The symptoms presented by C— do not remind one of the ocular stigmata of the Charcot school, but they fit well into the pcture of Babinski's pithiatism. Two successive emotional disturbances produced the condition: first the shock on the battlefield; secondly, the threat of being sent back to the firing line.

The ocular symptoms are, up to a certain point, capable of being produced voluntarily. Voluntary strabismus is well known, and, if we are not in a position to speak of voluntary anisocoria, the intimate relation existing between the two phenomena allows us to connect them pathogenetically and to claim that in C— they were manifestations of a mind more or less blunted. Thus the anisocoria might be the result of an unconscious associated movement accompanying a voluntary movement. We cannot positively exclude malingering, as the differentiation of malingering and pithiatism is always difficult. Nevertheless, the production of the phenomena described can take place only in a vitiated, desequilibrated subject.

The role of the supranuclear functional centers which coordinate the extrinsic movements of the eyeballs is well known both in its normal and pathologic modalities. We know that strabismus and nystagmus are the visible manifestations of the desequilibrium of these centers, generally brought about by secondary causes, ocular or other, and we must be careful not to confound them with pseudostrabotic deviations or nystagmiform oscillations, paralytic or spasmodic, with an organic base. The coordination of the agents of intrinsic ocular motility has received less attention. Nevertheless, the fact that in most people the pupils have the same diameter in spite of uneven illumination of the two eyes proves that this function of pupillary equality does exist; and, furthermore, the fact that with a given intensity of illumination the pupils vary with the accommodation, and convergence evidences the intimate relations existing between the coordinating center for the muscles of the pupil, the accommodation, and the extrinsic muscles. The persistence of equal pupils in many strabotics, in anopia, and in anisometropia, proves the relative autonomy of the pupillary coordinating function. The anatomic location of this pupillary center is hypothetic; physiologically it is superior to the nuclei of the oculomotorius, which are executive agents, and it is closely associated with the coordinating centers of the extrinsic muscles. It is inferior to the voluntary and reflex centers.

The tonic center of the conjugate pupillary movements, aside from the lateral connections (center of lateral movements, center of convergence, supranuclear center of accommodation) is found bordering on numerous centripetal paths, visual, auditory, vascular, cerebral, kinesthetic, etc. The executive agents are the dilators and sphincters of the pupils. The relation is maintained by the common oculomotor and the sympathetic system. A lesion situate anywhere along the centrifugal part of the system will provoke an organic anisocoria of the known paralytic or spasmodic type; a lesion or irritation at any point of the centripetal system or of the lateral connections will not provoke an anisocoria, providing that the coordinating center displays sufficient activity. If the center is miopragic (underfunctioning) these secondary causes may determine an inequality of the pupils. Functional insufficiency is the basal cause, and this fact justifies the use of the term which we have adopted of "functional anisocoria," in analogy to the term "functional strabismus," in both conditions desequilibrium of the neighboring centers being present.

An understanding of the lateral and afferent connections of the pupillary center will serve to explain the secondary types grafted on functional anisocoria to produce the various clinical modalities. When an underfunctioning pupillary center comes under the

domination of a coordinating center of convergence which is desequilibrated we shall have synchronism of functional anisocoria with functional strabismus, as in our patient C—.

Observation 2. In an aviator aged 22, with negative history, except that of a convergence of the left eye of 15° dating from childhood, and with vision of 6/6 in either eye, the pupil of the left eye was constantly smaller than that of the right eye. This inequality of the pupils in no way interfered with the voluntary or reflex reaction of the iris. Examination of the nervous cerebral, and sympathetic system, radiographic examination of the mediastinum, Wassermann reaction of the blood, all negative. Here again, we see the desequilibrium of the center of convergence entailing a desequilibrium of the neighboring pupillary center. This condition, altho it arose early in life, is not entitled to the name of congenital anisocoria or congenital strabismus.

The association may be a little looser; the anisocoria may outstrip the desequilibrium of the centers of the extrinsic motors, so that the anisocoria is permanent while the strabismus is latent, thus giving, on superficial examination a picture of true physiologic anisocoria, or of the congenital type mentioned by certain authors. The use of a screen will quickly reveal the true state of affairs by converting the latent into manifest strabismus.

The possible occurrence of a triad of symptoms: strabismus, nystagmus and anisocoria is shown here.

Observation 6. R—, aged 24, with 0.3 in the right and 0.1 in the left eye after correction, shows concomitant internal strabismus of the left eye; permanent horizontal nystagmus with slow, narrow oscillations when binocular vision is used, and quick wide oscillations when monocular vision is employed. Unequal pupils under all conditions; under candle light in a dark room the right pupil measures 4 mm., the left 5 mm. Reaction to light well marked on both sides, and good to convergence. Besides there is hippus with wide oscillations. Thus we see that anisometropia will produce anisocoria in subjects in whom the pupillary coordinating center is below par under the same conditions under which a convergent or a divergent strabismus is due to an occasional ametropia. This brings us to the much debated question of unequal pupils due to anisometropia; while some writers deny the existence of an anisocoria of this type, others maintain that it exists, and still others see in it either a physiologic anisocoria, or a congenital morphologic or structural anisocoria. The authors believe that uncomplicated anisometropia is unable to produce anisocoria any more than it can produce strabismus, unless there be some profound anomaly of the centers of coordination, be it of the internal or of the external motor apparatus of the globes. There must be some, however slight, defect of the nervous function. Stimuli may be transmitted from a distance through the connections of the pupillary coordinating center. The influence of the cerebrum, more or less consciously arising, is seen in the case of C. Amongst the sensorial stimuli the most important are those of the visual order. In otherwise normal subjects the greatest variations of illumination will not give rise to pupillary inequality; in subjects under the domination of anisocoria the smallest variation in illumination or the slightest macular lesion will precipitate the functional syndrome. As Roche says: "In lesions of the chorio-retina situate at or near the posterior pole, the pupils are uneven, the pupil of the affected eye being the wider. This anisocoria is always of low degree and the pupillary motility remains intact." The authors think it would be more logical to assume a latent desequilibrium of the coordinating centers of the pupils, the anisocoria becoming manifest when the retinal sensorial inequality precipitates it, just as in eyes which become strabotic late in life through a tardy amblyopia, or as nystagmus appears after the loss of binocular vision.

Again, we meet equal pupils in subjects with severe optic or retinal lesions. In these cases the center of

equilibration is doing the work that was cut out for it. A nurse aged 25, whose left eye had suffered a contusion without visible rupture of the tunics, underwent a reduction of vision in the injured eye until a mere perception of light remained. No response to direct light stimuli, but perfect response to indirect light stimuli and to convergence. The pupils were even at all times.

In conclusion the authors draw attention to a form of anisocoria which they style "matutinal functional anisocoria." This form appears in individuals who have been educated to autoobservation. It comes on after awakening, and is very intense for fifteen to twenty minutes. In spite of its intensity it is highly transitory and disappears after ocular movements or reading. It cannot be provoked by artificial differences of retinal excitation, nor does it lead to any definite new trouble. The iridic functions are perfect.

M. W. F.

Berner, O. A Case of Sarcoma of the Iris. Norsk Magazin for Laegevidenskaben v. 79. No. 12.

The writer presents the clinical and microscopic findings of a case of sarcoma of the iris and gives his theories as to the development of these tumors. The patient was a woman of 37 years of age who presented herself on account of a sudden dimness of the vision of the left eye which however had disappeared over night. The writer explains this symptom by supposing a possible hemorrhage from the tumor into the anterior chamber.

Clinical examination showed a lens-shaped almost round elevation of the iris of about 2.5 mm., diameter at the pupillary margin below in the left eye. It was heavily pigmented, dark brown, while the general color of the iris was bluish gray The iris had besides small brown spots thruout. The patient stated that she had always had a brown spot below the pupil. No vascularization could be made out even with a strong loupe nor could any adhesions to the lens be found. Transillumination of the ciliary region was negative. There was no conjunctival injection, media were clear, fundus negative, and no increase in tension.

A complete iridectomy downward was done. The microscopic picture showed a marked cellular proliferation in the stroma of the iris, especially at the pupillary edge, characterized by small, dark, evensized spindleshaped nuclei. A few sections showed typical giant cells, but in none could any polynuclear leucocytes be found. Pigment cells of two types were very numerous in some sections, the first type a large round cell so heavily pigmented that the nucleus was obscured, the other a smaller cell with a variable amount of pigment. By using Alfieri's method of removing the pigment a differentiation between the retinal and stroma pigment cells was obtained. The author also convinced himself of the presence of "Klumpcellen" in the stroma. All in all the microscopic appearance reminded one very much of that from Casey Wood and Brown Pusey's case.

The author discusses at some length the theories as to development of sarcoma of the iris. Other writers have traced a relationship between the pigmented spots of the iris and sarcoma. It has been pointed out that these pigmented spots are separate and distinct from the regular coloring of the iris In structure these pigment spots consist of socalled "Klumpcellen," large round cells very heavily pigmented; and differ markedly from the small pigment cells of stroma of the iris. He believes that these "Klumpcellen" are really retinal cells detached during embryonic growth and pushed into the stroma layer.

In support of this theory he points out that these cells are most numerous in the posterior region of the iris and also at the pupillary border at which latter place he assumes they are detached at the same time as the retinal cells which go to form the muscle of the sphincter of the pupil. The stroma cells are of mesodermic, while the retinal are of ectodermic origin and hence these pigmented spots which are supposed to give rise to malignant growths

are epithelial in character. This theory may explain the fact that sarcoma of the iris in distinction from other sarcomas, appears mostly in middle life, around the age of 40, and also that this tumor has a predilection for the lower half of the iris, a phenomenon formerly thought entirely accidental, but now assuming some significance in relation to the location of the choroidal fissure.

The iridectomy was done in August, 1916. In April, 1918, no recurrence had taken place.

D. L. TILDERQUIST.

Young, George. Threshold Tests. British Journal of Ophthalmology, July and August, 1918, p. 384 and 430

The writer calls attention to the fact that altho the probable diagnostic importance of the determination of the approximate thresholds for light differences and colors has been pointed out, very little accurate knowledge in this field has been worked up; he suggests that investigations of the subject should be undertaken and notes compared; he offers a rapid and accurate procedure which can be employed by the busiest workers.

The test objects consist of pieces of white blotting paper upon which are produced spots of black, red, green, blue and yellow in dilutions equalling 1/512, 1/256, 1/128, 1/64, 1/32, 1/16, 1/8, 1/4, 1/2 and I, each successive spot being double the intensity of the previous one; for pigments the Windsor and Newton's waterproof inks commercially known as India ink, vermillion, emerald, ultramarine, and yellow are used, the dilutions made in distilled water, and dropped from a pipette of 1 mm. drop surface, from a height of 100 mm. Fifty cards are fastened in the above order both of color and dilution, on each grey page of a photograph album and the value of each card noted in a corner.

The patient must sit so that a good source of daylight strikes the pages of the album obliquely, coming from behind and one side, and the cards are successively presented in the above order before each eye separately, one card at a time. At each card the surgeon asks: "blank or spot?" The black series coming first, gives a rapid clue in cases where the light sense is diminished. The palest black spot recognized is noted as the nearest to the threshold for differences of light intensity. Where this threshold is at fault with no scotoma, those who have a good photometer should use it and help decide whether the light threshold is also at fault in all cases. If this is the case—and Young thinks there is little doubt about it—the test with the black series becomes a direct test of the light sense.

With the color series the same process is performed until the patient answers "spot," when the surgeon must immediately say: "any color?" The palest spot evoking a color sensation, though misnamed, is noted as the nearest to the threshold for that color. In testing for red and green it is often a good plan, after having exposed each card successively on two opposing pages, and no color has been perceived, to uncover both, testing for scotoma.

Young finds the threshold for light differences and that for color coincide invariably, as has been pointed out, but they often vary for the other colors, and "spot" is announced one or two cards before color sensation is evoked; he believes there is little doubt that these color thresholds will frequently prove to be the only pathologic sign, when color vision and field are normal.

A fairly large number of observations shows the following averages in normal eyes, seldom varying to any marked degree: black, 1/512; red, 1/256; green, 1/32; blue, 1/512; yellow, 1/256. With both eyes exposed the thresholds are about twice as keen; ordinary variations of daylight do not matter; reflections interfere and consequently the light should be well chosen and uniformly adhered to; ordinary artificial lights should be avoided tho electric light with suitable bulbs may prove satisfactory.

Rapidity is not only possible, but essential, especially where the color dots are concerned, in order to avoid the element of afterimages creeping in, with the confusion that would re-

sult. To go thru each set rapidly and urge the patient to prompt attention and quick reply, and to pause between each set while noting the number, will eliminate the complication. After very little use, the album test does not take two minutes.

The writer adds a table giving a number of clinical examples which, although too scanty to draw conclusions, are often striking. Thus in a case of hemorrhagic retinitis, yellow is not seen until saturated, while in an example of disseminated choroiditis this color is seen with 1/256 dilution. Interesting also is the reduced light sense, as compared with the color sense, in three examples of glaucoma and the reverse condition in two instances of optic nerve atrophy in which the light sense is only affected very late. Tobacco amblyopia is diagnosed with great rapidity with the red and green cards, the patient at once seeing the color on the opposite page, while missing it on the one he is looking at.

Macphail, James N.—Importance of Some Minor Eye Operations. (Indian Medical Gazette, June, 1918.) This is an address delivered at the Bengal Branch of the Medical Missionary Association of India. The writer has had a very large experience of eye work in India, and in this paper makes a few remarks about eye operations in general. Speaking of tattooing the cornea and the puncturing of thin scars that sometimes occur, he says that if proper antiseptic precautions have been taken it may do good by relieving tension and preventing the formation of a staphyloma.

Trachoma calls for operative treatment usually. Expression converts a chronic into an acute condition, which is more amenable to treatment. After expression he applies a one per cent solution of corrosive sublimat to the new surface, following Treacher Collins' method. Entropion he treats by splitting the lid and removing a wedge of skin from the skin surface of the lid. Grafting is not done apparently.

Iridectomy Mr. Macphail thinks the operation for acute glaucoma, and he is inclined to doubt if a glaucoma that is not benefited by iridectomy will benefit by an other operation. His experience is that any operation in chronic glaucoma is unsatisfactory. When patients come with a ripe cataract in one eye, he extracts it; and at the same time does a preliminary iridectomy in the other eye. He would do this in all cases if he could.

Musy, T. Tuberculosis of the Conjunctiva Caused by a Bacillus of the Bovine Type. (Ann. d'Ocul., Mar., 1918, Vol. CLV, p. 144.) A case of tuberculosis of the conjunctiva resembling Parinaud's conjunctivitis was described in 1914. It was not possible at that time to say whether the germ was of the human or bovine type. But by making use of the fact that human tuberculosis produces in cattle only localized infection, at the point of inoculation, while the bovine type rapidly develops into a generalized tuberculosis, the author was able to demonstrate that the germs in his case were of the bovine type.

LESSONS FROM SCLERAL TREPHINING.

The report by Dr. A. E. Ewing of a case subjected to postciliary scleral trephining for acute glaucoma, (Jour. A. M. A., Dec. 14, 1918), is interesting not only from the operative point of view, but more especially from that of the physiopathology of glaucoma.

The patient, a woman 57 years old, had in the right eye the visual field confined to the temporal side, and very much restricted. Tension with Schiötz tonometer equalled 57 mm. Hg., Vision, 8/150. Myotics failing to control the disease, a postciliary scleral trephining was performed, in the upper temporal portion of the eye. After dissecting a conjunctival flap down to the sclera, a 2 mm. trephine was applied and a hole made in the sclera alone, leaving the choroid intact. The conjunctival flap was then replaced and sutured.

There was no appreciable reduction in the tension following the operation, as determined by palpation. Forty-eight hours later the globe was quiet and the cornea clear, but vision was reduced to counting fingers at one foot. During the following four weeks, with the aid of eserin, vision rose to 20/60, but there was marked protrusion of the conjunctiva over the wound. The opening in the sclera could readily be seen through the conjunctiva and shown to be clear by transmitted light.

Three weeks later, the tension had risen to 60 mm. Hg., and vision lowered to 20/120. The protrusion on the conjunctiva was excised, showing a dense fibrous tissue which blocked the aperture. After removing it, the choroid was slit open and from the incision three large drops of vitreous escaped leaving the globe very soft. V = fingers.

One week after this second operation tension was only 9 mm. Vision rose to 20/240. Within a month tension rose to 51 mm., and vision lowered to motion of the hand at six inches. With the use of eserin the media cleared and V=20/250. A marked protrusion of the conjunctiva was again noticed on the wound, which being incised al-

lowed a free flow of aqueous, but no vitreous, and tension was reduced to below normal. Three days afterward the patient was very uncomfortable, the eye being hard and the fundus blurred. The conjunctiva distended; incision gave immediate relief, the sight rising and the media clearing. Three days after the puncture the patient felt severe pain. A new incision produced a free discharge of aqueous, but no vitreous, and immediate relief from pain. Scleral trephining in the same place revealed a new fibrous scar, a free escape of aqueous, no vitreous, was produced; tension lowered to normal and vision rose. But the same symptoms recurred.

Three months later trephining was performed on a fresh spot of the sclera. Finally the sight was lost entirely, and tension rose to 70 mm.; but the eye was quiet and comfortable.

The conclusions which can be drawn from this case are: 1st. That scleral trephining as an operation for the relief of subacute glaucoma, even with slitting of the choroid, is entirely useless, because the wound is rapidly closed by newly formed fibrous tissue, which interferes with the proper drainage of the eye. 2d. The cloudiness of the cornea and vitreous, and the arterial pulsation, can be instantly relieved by drainage from the vitreous, with immediate restoration of the sight. 3d. The loss of vitreous even in such quantity as to leave the eye very soft, is no more cure for glaucoma than is the removal of the lens. 4th. A drainage of the aqueous can be established from the anterior part of the eye through the vitreous and below the conjunctiva.

It is an established fact that the vitreous is never reproduced, its loss being always compensated by a quantity of aqueous which takes its place. For that reason it is not unusual in our opinion, that no vitreous escaped after the incisions of the conjunctiva and choroid. What makes this case interesting is the striking fact that glaucomatous symptoms were always produced when the aqueous accumulated in the eye, notwithstanding the small quantity of vitreous left. This proves that in glaucoma the secretion of the aqueous is not stopped, even when the intraocular pressure is very high, and also that when the anterior outlet is closed it accumulates in the vitreous sponge, and equalizes the pressure all over the eye, escaping freely when an artificial outlet is produced either forward or behind the equator.

It is to be regretted that Dr. Ewing had not made the chemical analysis of the aqueous which escaped after his numerous operations, with the object of ascertaining whether the composition was changed, and if a greater quantity of colloids, albumin, etc., existed. A fact which points to this altered composition is, that the media always cleared to a great extent when the eyeball was punctured.

M. Uribe-Troncoso.

WAR OPHTHALMOLOGY

The phrase, "War Ophthalmology," and its equivalents are used to indicate certain aspects of ophthalmic science and art, that have been rapidly developed or emphasized by war. The literature of the war period has been very largely devoted to ocular injuries, certain forms of which have been relatively very frequent. Yet the eye remaining unchanged, its reaction to external force is very much the same as in times of peace. Looking backward we can surmise from present experience, what took place in former wars; and for the future, the lessons now learned will have permanent value, and will be applicable in an era of peace.

The continuity of war ophthalmology thru successive ages has been treated by our ophthalmic colleague, Dr. James A. Spalding, in his presidential address on "The Eyes in War," published in the *Journal of the Maine Medical Association* for March, 1919. He says "In the beginning of the world, savages fought for similar reasons, and met with just that same sort of injuries around the eyes as are seen today, amongst savages hardly yet more civilized than our remote ancestors." With different weapons and

methods of attack, very much the same damage has been done to the combatants.

Again, as Dr. Spalding points out, the value of the eye, even a single eye, to the warrior, has been recognized in legend and history, in tapestry, and painting. The eyes of the fabled Argus are a prohpecy of the modern army with its observation service. It is extremely interesting to trace, as Dr. Wood has done (p. 220 of this volume) and as Dr. Spalding does in his address, the history of the eye in previous wars.

Dr. Spalding cites Baron Larrey with regard to the Napoleonic wars. His own study of eye injuries during the American Revolution and the War of 1812 reveals nothing more serious than burns of the eyelids and eye from flashings of powder from old-fashioned flintlock muskets or from bits of flint itself." In the American Civil War, the number of cases of sympathetic ophthalmia was notable. Many eyes were injured by buckshot, and shell explosions began to figure as an important cause.

In the Franco-Prussian War of 1870 ophthalmology was recognized as a special branch of surgery. "Soldiers with eye injuries were for the first time carried to the rear and put in charge of ophthalmic surgeons. The left eye was hit more often than the right, due, as was surmized, to the better protection furnished to the right eye by the butt of the rifle. It was now observed that if an eye suppurated after an injury, it was much less likely to induce sympathetic ophthalmia than if insidiously inflamed. Sutures were also now first utilized for sewing over extensive injuries of the sclera, and with unlooked-for good results, many an enucleation being thus avoided. A man of whom I lately heard, lost the sight of an eye totally, the bullet lodging in the orbit and only being removed at death, thirty years later. In another instance, a soldier was hit in the right eye, without apparent injury, but could afterward 'see but half of objects with this eye.' Dynamite and gun cotton explosive injuries were studied, and strychnia utilized hypodermically for optic atrophy following concussions without material injuries. Much was said of the early or late operations for traumatic cataract, and first aid bandages, covered with aseptic ointments, for protecting orbital, eyelid, or other injuries, were utilized in military surgery at this time."

Dr. Spalding goes still more extensively into the lessons that have been learned since 1914, and especially the limitations of the value of our usual tests for visual acuity, color vision, and the equilibrium of aviators. He also takes up the reeducation and provision for the war-blinded.

His interesting address fully establishes the claim thus expressed, "Without detailing a hundredth part of all that might be said concerning the eyes in war, let me here reiterate the main idea of this paper that from time immemorial the eyes have been injured in quarrels of all sorts, and that as such injuries occurred, methods of defense were invented. In spite, however, of all that we can do, injuries will occur; so that the study of their cure will forever be worth the efforts of the keenest minds in medicine."

E. J.

OPHTHALMIC EXAMINATIONS.

The American Board for Ophthalmic Examinations will hold its next examination at the Wills Eye Hospital, Philadelphia, 3 P. M., Friday, June 6, 1919.

This examination will be the fifth to be conducted by the Board. The Board is composed of representatives of the American Ophthalmological Society, the Section on Ophthalmology of the American Medical Association, and the Academy of Ophthalmology and Otolaryngology. By arrangement with the American College of Surgeons, the Board has become the Ophthalmic Credentials Committee of the College, and conducts the examinations of the ophthalmic candidates for Fellowship in the College.

For a certificate of this Board, the examination in ophthalmology consists of first, case records; second, written

examinations; and third, clinical laboratory and oral examinations, or so much thereof as may be adjudged necessary:

(a.) Candidates in ophthalmology are required to submit twenty-five complete case records of which not more than ten should be descriptive of operations. These records should be of cases of ocular diseases and defects of varied character, including errors of refraction or muscle balance; external ocular diseases or diseases of the uveal tract or retina, or of the optic nerve, or glaucoma. The reports should show especially the reasons for the diagnosis, and for the operative treatment and the technic of operations in operative cases.

(b.) The written examination will test the candidate's knowledge of the underlying principles of the science of ophthalmology, including anatomy, embryology, physiology, physiologic optics, pathology, relations of the eye to the other organs and diseases of the body.

(c.) The oral examination will include: The external examination of the eye. Ophthalmoscopy (candidates are requested to bring their own ophthalmoscopes). Measurement of errors of refraction. Testing of the ocular movements and fields of vision. Relations of ocular conditions to diseases of other parts of the body and their treatment. Laboratory examination in histology, pathology, and bacteriology of the eye.

Further information may be had upon request from the Secretary, Dr. William H. Wilder, 122 South Michigan Avenue, Chicago, Illinois.

SOCIETY MEETINGS.

The annual meeting of the Ophthalmological Society of the United Kingdom, Great Britain and Ireland was held this year, May 1-3.

The Société Française d'Ophtalmologie resumed its series of annual meetings at Paris, May 5th. Dr. F. Terrien made the report on the special subject for discussion on X-Ray and Radium in Ophthalmology.

The following meetings will be held:

Section on Ophthalmology, American Medical Association, Atlantic City, New Jersey, June 9-13.

American Ophthalmological Society, Atlantic City, New Jersey, June 13-17.

Oxford Ophthalmological Congress, Oxford, England, July 10-12.

Pacific Coast Oto-Ophthalmic Society, San Francisco, California, August 4-6.

The Colorado Congress to be held August 4th and 5th will this year include both ophthalmic and oto-laryngologic papers and discussions.

American Academy of Ophthalmology and Oto-Laryngology, Cleveland, Ohio, September 1-3.

BOOK NOTICES.

Atlas of Military Ophthalmology (Atlas der Kriegsaugenheilkunde samt begleitendem Text), by **Prof. A. von Szily,** Freiburg, i. Br.; large 8vo.; pp. 195-354, 2d part; plates XVI to XLVII. F. Enke, Stuttgart, 1917; also numerous black and white illustrations in the text; 20 marks.

This is the second of the proposed three sections of von Szily's Atlas, the first one having been published early in 1917, reaching this country some six months ago. The final one advertised for issue also during 1917 has not yet appeared.

The text of the first part of this excellently planned monograph is divided into four chapters; the present part carries the work to the eleventh chapter.

The fifth chapter is concerned with gross lesions of the eye associated, of necessity, with other extensive wounds. Two of the accompaniments of these large traumatisms are enophthalmus and exophthalmus, a subject begun in the first part of the Atlas and ended in the second. Shrapnel wounds of the face, of the walls of the neighboring cavities and of the skull (with ocular injuries), are the commonest examples. These are well illustrated in the text and the treatment—especially in the surgical conduct of the cases—

is fully outlined. One of the outstanding attractions of the chapter is a description of the fundus appearance in several cases of gross injury, which are well reproduced in color.

The pulsating form of traumatic exophthalmus is extensively described and its incidence compared with the experience of the Russo-Japanese War and with civilian occurrences.

Chapter seven deals with metastatic ophthalmia in the war. Von Szily's experience is much the same as that of British and French observers; in spite of conditions supposed to favor the production of this distressing complication, it has been one of the most uncommon sequels of systemic poisoning. Four cases, each with a complete history and histologic report, are given which do not, however, differ essentially from the well known picture of the disease depicted in our text books —the panophthalmitis of pyemia. It may be added that, as in civil life, the double sided ocular metastases, of whatever origin ended almost invariably in the death of the patient.

Axial wounds (Durchschüsse) are naturally found in infantry organizations and consist largely of bullet wounds, but not infrequently the thru-and-thru penetration is the result of shrapnel. Most of these traumas in survivors are lateral or oblique; anteroposterior shots penetrate the brain and cause almost instant death. In these cases it is of course the fundus changes that interest one and the reproduction of the background alterations, altho in the Atlas too highly colored, are admirable. It is remarkable to note the successful efforts made by nature under aseptic conditions, to close the wound by extensive cicatrization, and how well these are shown by the ophthalmoscope.

In this chapter is also shown by numerous diagrams, the narrow escapes (except by neighborhood shock), the eyeball suffers in engagements where the whole atmosphere seems charged with flying bullets. These missiles enter and leave the orbit at all possible angles, sometimes without any permanent injury to eyesight.

The eighth chapter is devoted to bilateral injuries of the globe, mostly from shrapnel.

Chapter nine deals with the war blind (due to wounds) in general. These are (practically) all the result of serious bilateral injuries. Oguchi found 53 such cases in a total of 3,781 ocular injuries in the Russo-Japanese war. Probably the proportion will be about the same in this great conflict, but complete German-Austrian figures are not yet available.

The next chapter deals with perforating wounds of the eye and with foreign bodies in the globe, especially in relation to infection and sympathetic ophthalmitis. Here again the Allied experience is duplicated. Probably owing to early treatment and to the fact that most of the missiles are aseptic, sympathetic disease has been exceedingly rare, probably more uncommon than in any previous war. When it did occur the picture presented is the classic picture familiar to our readers.

We look forward with interest to the final volume of this valuable series.

C. A. W.

The third part of this work containing pages 355 to 590 and giving the last six chapters, has just been received in this country. It reports a summary of the ophthalmic observations and therapeutic procedures for war injuries at the Freiburg clinic up to the spring of 1916, with a brief appreciation of it by "Herr Geheimrath Professor Dr. Th. Axenfeld."

The scope of the work is shown by the subjects of the different chapters, which are I, Cranial Shot-wounds and the Eye; II, Temporal Orbit Wounds; III, War Hemianopsia; IV, Penetrating Wounds of the Orbit and Vicinity; V, Lesions from Shot with Great Destroying Ability; VI, Metastatic Ophthalmia after War Wounds; VII, Penetrating Wounds, with Ophthalmoscopic and Histologic Findings of Chorioretinitis Proliferans and Atrophy; VIII, Bilateral Wounds; IX. Blindness Produced by Warfare; X,

Perforating Wounds of the Eyeball, Intraocular Foreign Bodies and Infections; XI, Macular Changes, Contour Shot Wounds, Contusion and Aerial Shot Wounds; XII, Effects of Gassing, Wounds and Burns from Gassing, Gas Grenades, Fire Bombs, Pistols for Flashing Light, etc.; XIII, Organic Lesions of Mobility and Sensibility with Remarks on the Psychognostic Reduction of Function in Skull Wounds; XIV, Psychogenic War Neuroses; XV, Wounds of the Nasal Sinuses and the Tear Duct; XVI, Plastic Operations in War Wounds.

Each chapter is accompanied by an extended bibliography; and excellent indexes of topics and authors mentioned are appended. The well known talent of von Szily for detailed description is nowhere more appropriately applied than to the description of the clinical characters of ocular injuries.

The mechanical execution of this work is fully up to the standards attained in Germany before the war. The paper is about twice as heavy as that used in this journal; and is highly finished to take perfectly half tone reproductions and color printing.

The whole appearance of the work, with its costly paper and wide margins, is strongly in contrast with the economies forced on the scientific publications of allied countries during the later years of the war.

The hope expressed by Axenfeld, June, 1916, that "this work will be an evidence of our activity in this great time," might apply more widely than as a mere record of the work of the Freiburg clinic.

The last two chapters, illustrated by 130 half-tone pictures of cases, given as they appeared after injury, with results of the "activities" that repaired these deformities, are a hint of the activities that produced them.

E. J.

Transactions of the American Academy of Ophthalmology and Oto-Laryngology, 1917-1918. 8vo, 606 pages, 1 colored plate, 111 illustrations. Published by the Academy.

Owing to obstacles and delays due to the war, when the twenty-third annual meeting of the Academy was held in Denver, last August, the printing of the proceedings of the Pittsburgh meeting, held over nine months before, had not been completed. It was therefore natural to combine the proceedings for the two years in a single volume.

This makes the largest volume of Transactions that the Academy has yet issued; altho each year it was suggested that the annual meeting be omitted because of the difficulties of securing papers for the program. We believe that in scientific value the papers here published will compare favorably with those in any of the preceding volumes.

The part of the volume relating to ophthalmology includes 350 pages. Most of the papers here printed have already appeared in the journals, some of them from the last meeting in the American Journal of Ophthalmology. In general form and makeup the volume corresponds closely to its immediate predecessors.

E. J.

CORRESPONDENCE.

The Electric Ophthalmoscope Mirror.

To the Editor:

In the discussion of the article "An Improved System of Illumination for the Electric Ophthalmoscope," by Dr. Carl Koller in the 1918 volume of the Transactions of the American Ophthalmological Society, the reader of the paper states that "the illuminating system used in the instrument sold as the 'May Ophthalmoscope' is the one that was worked out by myself and Mr. R. H. Wappler;" he claims that he has used a similar instrument in his office since 1911 or 1912, and he seems, apparently, to imply that I obtained some of the ideas embodied in my instrument from him or Mr. R. H. Wappler.

I wish to state emphatically that I owe nothing either to Dr. Koller or to Mr. R. H. Wappler in connection with this instrument.

I exhibited and described this ophthalmoscope at the meeting of the

American Ophthalmological Society in 1913, at the meeting of the Ophthalmological Section of the American Medical Association in 1914, at the December, 1914, meeting of the Ophthalmological Section of the New York Academy of Medicine, and at a meeting of the Metropolitan Medical Society of New York in 1913 or 1914. Surely these meetings ought to have given the reader of the paper referred to excellent and abundant opportunity for presenting his claims four years ago.

In 1912, tired of replacing broken mirrors in the electric ophthalmoscopes then on the market, I worked out a model, the essential feature of which was a solid piece of glass which acted as a mirror and was unbreakable. I made my model myself, even to the grinding of the reflecting prism; this model was given to the Wappler Electric Co. as a pattern.

I am not concerned and do not care about priority; if this were the only question involved I would not take up your space in replying to Dr. Koller's insinuations. When Dennett brought out his electric ophthalmoscope, with its basic innovation, he became entitled to about all the credit that can be attached to the instrument. The improvements which my instrument presents are merely details contributing more perfect illumination, convenience and durability. The improved system of illumination has been made use of in the urethroscope and cystoscope, tho I did not know of this until recently. Others had been working on the same idea; for instance in 1914, Dr. Harry Gradle of Chicago, wrote to me and said that my model was so similar to the one he had been working upon that he proposed to discontinue perfecting his.

Since my relations with the reader of the paper have never been cordial and for the past year or more have been "diplomatically severed," I was not even aware that he had constructed an electric ophthalmoscope which he kept in his office for his own use since 1912, without allowing his confreres to share in the advantages, if any, which might accrue from his ideas. Furthermore, I received no hint from the Wappler Electric Co., that they had had any relations with Dr. Koller in connection with an electric ophthalmoscope or else I would, under no circumstances, have given them my model for manufacture, since I had been negotiating with another concern in 1913.

CHARLES H. MAY.

New York City.

Glaucoma with Influenza.

To the Editor:

I have a case which goes to show the wide variation of untoward sequelae following influenza.

The patient, a woman of fifty-five years, presented herself one month after the onset of influenza with an advanced and pronounced glaucoma. Both pupils would not react to light, practically blind in the right eye, and vision reduced to 20/200 in the left; color fields very much reduced. She reports that shortly after she became ill with the influenza, she noticed a hardening of the eyeball. I had never seen so much diminution of visual acuity with glaucoma in so short a time, except in the fulminating type.

L. A. SCHIPFER.

Bismarck, N. D.

Infection Thru the Conjunctiva?

To the Editor:

During the post influenza period, at the time when a lot of talk was current "pro and con" the face mask as a means of partial protection, some one casually observed that not a great deal was to be gained by wearing a mask over the mouth and nose as a protection against droplet infection, because the eyes were a source of infection to the respiratory passages thru mechanical passage of organisms received in the eye and carried down thru the ducts into the nasal cavity, etc. We undertook some simple experiments here, inoculating the eye with easily detected organisms such as Prodigiosus, trying to recover the organism in various portions of the throat and nasal cavity. At

no time were we able to recover such organism.

Before we go into this further, we would like to inquire of your readers as to any work of this kind that has already been done. We are so shut off in this place from adequate library facilities that we continually fear that anything that we become interested in may have already been neatly and completely worked out—vastly better than we could possibly do it here. Would you then favor us with any citations to work of this kind, and also to any available data as to the germicidal or antiseptic action of tears.

CAREY P. MCCORD,
Major, M. C.
Base Hospital Laboratory,
Camp Sherman, Ohio.

NEWS ITEMS

Personals and items of interest should be sent to Dr. Melville Black, 424 Metropolitan Building, Denver, Colorado. They should be sent in by the 25th of the month. The following gentlemen have consented to supply the news from their respective sections: Dr. Edmond E. Blaauw, Buffalo; Dr. H. Alexander Brown, San Francisco; Dr. V. A. Chapman, Milwaukee; Dr. Robert Fagin, Memphis; Dr. M. Feingold, New Orleans; Dr. Wm. F. Hardy, St. Louis; Dr. Geo. F. Keiper, LaFayette, Indiana; Dr. Geo. H. Kress, Los Angeles; Dr. W. H. Lowell, Boston; Dr. Pacheco Luna, Guatemala City, Central America; Dr. Wm. R. Murray, Minneapolis; Dr. G. Oram Ring, Philadelphia; Dr. Chas. P. Small, Chicago; Dr. John E. Virden, New York City; Dr. John O. McReynolds, Dallas, Texas; Dr. Edward F. Parker, Charleston, S. C. Volunteers are needed in other localities.

DEATHS.

Dr. William Cheatham, of Louisville, Kentucky, April 3rd, from angina pectoris, aged 66.

Dr. Wallace Clark, of Utica, New York, March 16th, aged 69.

Dr. William Pearson Cowper, Edinborough, February 1st, aged 38.

Sir William Crookes, in London, April 5th, at the age of 86.

Sir James McKenzie Davidson, in London, April 2nd, aged 62.

Dr. Paul Herman Dernehl, of Milwaukee, at his home, March 28th, from diabetes, aged 40.

Dr. Osee Wallace Hoffman, in Denver, March 5th, of tuberculosis, aged 43.

Dr. R. A. Lundie, Edinburgh, December 18th, 1918.

Dr. E. H. Noble, Elmira, New York, March 6th, aged 53.

Dr. E. W. Nordensen, Swedish ophthalmologist, recently in Stockholm.

Dr. Frank Van Fleet, New York, April 5th, aged 58, of heart disease.

PERSONALS.

Dr. J. N. Reik, of Baltimore, has returned from France, and has resumed practice.

Dr. James E. Carroll, of Baltimore, has recovered from a recent attack of pneumonia.

Dr. Melville Black, of Denver, is spending a few weeks' vacation motoring in southern California.

Dr. Emory Hill, formerly of Chicago, has removed to Richmond Virginia, and opened offices in the Professional Building.

Dr. J. G. Linn, of Pittsburgh, Pa., is mustered out of the service, and resumed practice in the Highlands Building.

Dr. Wm. McL. Ayres, of Cincinnati, is still in France, connected with Base Hospital, No. 110.

Dr. H. H. Stark, of El Paso, Texas, has been honorably discharged from the Medical Corps of U. S. A., and has resumed practice.

Dr. James H. McKellar, of Pasadena, Cal., has reopened offices, 618 Title Insurance Building.

Dr. Charles P. Small has completed his term of government service and has opened offices in Suite 1111, Michigan Boulevard Building, Chicago, Illinois.

Dr. Thomas A. Woodruff, formerly of Chicago, announces his removal to New London, Connecticut.

Dr. Hans Barkan has been transferred from the Base Hospital at Camp Kearney to the Letterman General Hospital at the Presidio at San Francisco.

Dr. George U. Huber, of Coffeyville, Kansas, is convalescent after being ill eight weeks with influenza.

Dr. Harold Gifford, of Omaha, will be the guest of the Pacific Coast Oto-Ophthalmological Society meeting in San Francisco in August.

Dr. J. O. McReynolds, of Dallas, Texas, as president of the Medical Department of

the air service of the army, the Flight Surgeons' Association, presided over a meeting of the association, which met in Dallas, March 24-26.

Dr. Alan Kinisely, Jr., of Lima, Ohio, has just returned to that city from his army service.

Dr. Howard Hoyt Shiras, after completing his ophthalmic service at the N. Y. Eye and Ear Infirmary last year, was stationed at Camp Greenleaf. He has returned to Cleveland to resume his practice.

Major John R. Newcomb received an honorable discharge from the service April first, and has returned to Indianapolis to resume his practice. Upon his discharge, Dr. Newcomb received a commission as Lieut.-Col., in the Medical Corps.

Col. P. J. H. Farrell of Chicago, who has been commanding officer of two base hospitals in the advance sector in France, was recently in Germany on special duty.

The following Chicago ophthalmologists have completed their terms of army service and have resumed their private practice: Harry S. Gradle, Herbert Walker, E. K. Findlay, Sidney Walker, Jr., Chas. J. Swan, Chas. P. Small, Frank Brawley, G. W. Boot.

Dr. Edward E. Maxey of Boise, Idaho, has received his discharge from the service, and will resume his practice in association with Dr. R. L. Nourse.

Dr. L. S. Moore, who recently finished an internship in the Illinois Charitable Eye and Ear Infirmary, is now associated with Dr. P. A. Jordan of San Jose, Calif.

SOCIETIES.

At the meeting of the Section on Ophthalmology of the New York Academy of Medicine, March 17, papers were read by Lieut.-Col. G. S. Derby on "Eye Work with the British and American Expeditionary Forces," and Capt. G. H. Grant, "Restorative Surgery After War Injuries to Eyes." At its meeting of April 21st, papers were read by Dr. Alfred Wiener on "The Radical Treatment of Epiphora," and by invitation, Dr. C. R. Holmes, of Cincinnati, on "Extirpation of the Lacrimal Gland."

The Oxford Ophthalmological Congress, Sydney Stephenson, master, will assemble at Keble College, Oxford, on the evening of Wednesday, July 9th, next, and the meeting will be held on Thursday, the 10th, and Friday, the 11th, of July.

The first day, Thursday, the 10th, will be largely devoted to a discussion on "Preventative Ophthalmology," to be opened by Colonel J. Herbert Parsons, A. M. S., consulting ophthalmic surgeon to the forces. Members intending to take part in the discussion are requested to kindly send in their names to the honorary secretary at their early convenience.

The second day, Friday, the 11th, will be given up to papers, demonstrations, and cases, etc. It is hoped that members will make every effort to contribute to the success of the meeting with cases, specimens, new operations, or novelties of any kind. If, therefore, you have any such that you are willing to bring forward, will you kindly notify the undersigned at the earliest opportunity and your contribution will be welcomed.

The annual general meeting will be held in the evening of Thursday, July 10th.

BERNARD CRIDLAND,
Hon. Secretary.

At the meeting of the Chicago Medical Society on May 7th, Dr. Cassius Westcott read a paper on "The Relation of the Teeth to the Eyes."

Dr. P. A. Jordan of San Jose, Cal., was elected Chairman of the Eye, Ear, Nose and Throat Section of the California State Medical Society, held at Santa Barbara, April 15-17.

On May 12th the Chicago Ophthalmological Society held its last meeting until October. The program consisted of papers and discussions on various Compensation Tables for Eye Injuries.

MISCELLANEOUS.

The St. Louis Medical Society has appointed a committee to organize clinics in that city for the purpose of establishing a method of work to be done in each clinic from day to day in order that the local profession and visiting physicians may have opportunity to observe work done by St. Louis physicians. Dr. E. H. Higbee, Jr., has been appointed chairman of the Committee on Ophthalmology.

CONGENITAL EYE CONDITIONS (MIDDLETON)

AMERICAN JOURNAL OF OPTHALMOLOGY

Vol. 2 JUNE, 1919 No 6

CONGENITAL EYE CONDITIONS AFFECTING VISION OUT OF TWO HUNDRED THOUSAND TROOPS EXAMINED AT CAMP TRAVIS, TEXAS.

MAJOR A. B. MIDDLETON, M. C., OCULIST SPECIAL MEDICAL EXAMINING BOARD.

PONTIAC, ILLINOIS.

This abstract from the official report describes the conditions observed, with colored plate of the most unusual, and half-tone reproduction of sketches of some of the others. Authority to publish granted by the Board of Publication, S. G. O.

More than two hundred thousand troops were examined at Camp Travis, Texas, before the armistice was signed. Out of the eye cases referred to the Special Medical Examining Board, twenty-eighth had a congenital condition of the fundus or bulb causing a reduction of vision.

The cases were carefully sketched and the congenital defect painted in duplicate shades as per the water color drawing accompanying each history and description. The small number of congenital conditions affecting the bulb and fundus sufficient to reduce vision, taken from a large number of young men in the prime of life must not be misleading and give the impression that congenital eye changes are rarely met in civil life.

No doubt there were many afflicted with congenital eye conditions in this group of troops, who had sufficient vision to pass the regular examining board. The Local and District Boards prevented many from entering the army with insufficient vision, a certain percentage of whom had a congenital defect. These two facts explain the small percentage of cases found.

Time and space will not permit the discussion of each case separately, but the history and description gives all the details. It is strange to note, we found few duplicates.

An interesting thing in the history of congenital eye conditions that affect vision, is the fact that few of those thus afflicted have their eyes examined to determine the cause of poor vision. In this series of twenty-eight cases only one had consulted a doctor with regard to his eyes. Never having had normal vision, they do not realize the handicap from which they are suffering.

CASE 1. MULTIPLE SCLERAL ECTASIA. Private T. J. R., June 28, 1918. Denies specific history. Right eye has not given trouble other than the dimness of vision; did not have eyes examined by a doctor before entering the army; no history of receiving a hard blow over the right eye.

Examination. Age 22 years; white; vision O. D. 10/200; O. S. 20/20; no squint; tension normal; right cornea clear and free from scars; anterior chamber deep. Aqueous clear; iris free from adhesions and deposit of pigment. Lens clear: Vitreous clear and not fluid. Macula normal. Temporal side of the field dark. At the disc is a large circular coloboma of the choroid, the diameter of which is equal to twice the diameter of a normal disc. Directly below the coloboma of the disc, separated by an isthmus of normal choroid, retina and sclera, four millimeters wide, is a second circular coloboma of the choroid, two-thirds the diameter

of the one at the disc. The inferior retinal arteries and veins are displaced, passing directly downward from the disc, over both colobomas of the choroid. There is a band of exposed sclera four millimeters wide, within the circumference of each choroidal coloboma, with a sharply pigmented inner margin. The pigmented line is on the outer margin of the congenital hole in the sclera. The depth of each scleral ectasia or pocket is three diopters. On the floor of the scleral ectasia the retinal and cilio-retinal vessels pass over a smooth surface, bending forward over the margin of the scleral hole, continuing on a second, level surface of sclera, exposed by the choroidal coloboma. At the margin the retinal vessels bend forward to the normal level of the retina. The retinal vessels are on the bottom of each hole proving that the retina is intact even tho the choroid is absent. The larger vessels pass into and directly across each hole. The isthmus of retina and choroid between the two holes is normal, having a width of three millimeters. The chorio-retinal vessels are present on the nasal side of the disc but are absent on the temporal side. No choroiditis or choroidal ruptures. Considerable deposit of pigment in the choroidal coloboma area, but an absence of pigment in the bottom of the scleral coloboma or ectasia. The scleral coloboma in both places is larger at the bottom than the top, the vessels disappear before they pass out of the scleral pocket over the choroidal coloboma margin, the same as in an advanced case of glaucoma. The vessels in the upper half of the fundus are normal in size and position. See Fig. 1.

Case 2. Opaque Nerve Fibers. Private C. S., May 1918. Left eye has never given trouble other than reduced vision. Had not had the eye examined by a doctor, before entering the army. Denies specific history. No history of poor vision in the family. Parents not related.

Examination. Tension normal. No squint. Vision O. D. 20/20; O. S. 20/200; right fundus normal. Left cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from adhesions and deposit of pigment. Lens clear and normal. Vitreous clear and not fluid. Vessels normal. Macular area normal. Disc normal in size and color except the upper half. Extending upward from the center of the disc is a fan-shaped splash of opaque nerve fibers one disc diameter in width over the retina. The opaque fibers cover the retinal vessels almost entirely, but do not follow their course. No choroiditis or rupture of choroid. Field of vision normal. No congenital pigment deposit.

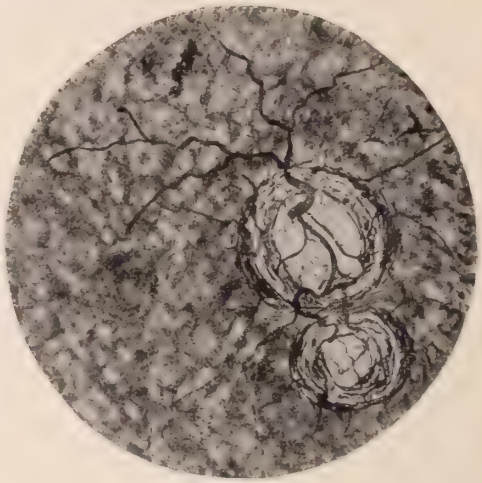

Fig. 1. Multiple Scleral Ectasia.

Case 3. Opaque Tissue on Optic Disc. Private S. H. E., April 5, 1918. Claims to have had syphilis early in life, but no symptoms or indications that the disease ever existed. Discharged from the army December 6th, 1917 (2nd draft) for beginning optic atrophy. During first induction this soldier malingered with regard to his eyes, pains in the body and several ailments, which he claimed were the result of syphilis early in life. After being in the hospital and held under observation for several weeks, was returned to his company. Discharge from the army for beginning optic atrophy, returned home, the local board reinducting him with the seventh increment. The same tactics were followed

in order to avoid the army on the second induction, stimulated with a recent discharge from the army due to optic atrophy. The supposed optic atrophy on a careful examination proved to be a duplicate congenital condition of each disc. The eyes never gave trouble in civil life.

Examination. Tension normal, vision O. D., 20/30; O. S. 20/20. Fields normal; each cornea clear and free from scars. Anterior chambers deep. Aqueous clear. Iris free from adhesions and pigment deposit. Pupils equal and normal in size, reacting normally to light and accommodation. Power of convergence normal; vitreous clear and not fluid. Vessels normal. No choroiditis. Lens clear. No change at the macular region. Discs normal in size but bulging resembling a pseudopapillitis. The nasal half of each disc shows ten or twelve elevated circular areas two millimeters each in diameter, giving the appearance of a white blackberry, these nodules do not extend farther than the margin of the superior and inferior retinal vessels as they pass over the disc, the temporal half of each disc being smooth, but bulging. The discs give a very white appearance, the nasal half with its opaque tissue confined to the disc, resembling in color an advanced case of optic atrophy. No pigment in or near the disc. The white elevated areas are confined to the disc and do not show the usual signs found in cases of exudative deposits. Fields normal. See plate VIII.

Case 4. Congenital Pigment in Physiologic Cup. Private C. M., July 5, 1918. Poor vision in left eye all of life. The eye has not given one moment's trouble other than reduction in vision. Has not had the eye examined by a doctor before entering the army. All members of family have good eyes. No specific history.

Examination. White; single; tension normal. No squint. Vision, O. D. 20/20; O. S. 10/200. Cornea of left eye clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from adhesions and deposit of pigment. Pupil slightly dilated reacting slowly to light and accommodation. Power of convergence reduced. Normal field of vision. Lens clear. Vitreous clear and not fluid. Vessels normal. No choroiditis or choroidal rupture. Disc normal in size and color. On the temporal side of the physiologic cup in the left disc is a densely pigmented triangular area. Each side of the triangle equals one-third the disc diameter in length. The pigmented area does not extend beyond the margin of the physiologic cup, but stops abruptly at its temporal margin. The densely pigmented area extends to the bottom of the physiologic cup. One apex of the pigmented triangle ends at the bottom of the cup, at the point where the central vessels enter the nerve trunk. The pigmented area is not elevated or nodular, but smooth and flat. No vascular disturbance near the pigmented area. No signs of a growth, like a melanotic condition might present. Cilioretinal vessels pass thru the pigmented area, which is nothing more than a congenital pigment deposit on the temporal side of the physiologic cup. See Plate VIII.

Case 5. Congenital Varicose Vessels. Private J. W., June 1918. Left eye has been weak all his life, but has not given trouble other than dimness of vision. Never had the eye examined by a doctor before entering the army. All members of family have good eyes. Specific history denied. No history of trauma.

Examination. No squint. Tension normal. Vision O. D. 20/25; O. S. 20/200. Field of vision normal. Cornea of the left eye clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from adhesions and deposit of pigment. Pupil normal, reacting to light and accommodation. Power of convergence normal. Lens normal. Vitreous clear and not fluid. Disc normal in size and color, as far as can be determined, there being a congenital varicosity of the retinal vessels in front of the disc. No evidence of arteriosclerosis. At the points where retinal artery and veins leave the disc, they are very tortuous, folding across the disc three times, extending forward

into the vitreous. The disc is not bulged. The veins are not compressed by the arteries. The vessels otherwise normal, continue in a normal position after leaving the margin of the disc. The varicosity is confined to the area in front of the disc. See Fig. 2.

Case 6. Congenital Pigmentation Left Macular Region. Private C. M. W., May 24, 1918. Age 23; occupation, farmer; single, white; left eye weak all of life; never had it treated or examined by a doctor; the eye has not given one moment's trouble other than

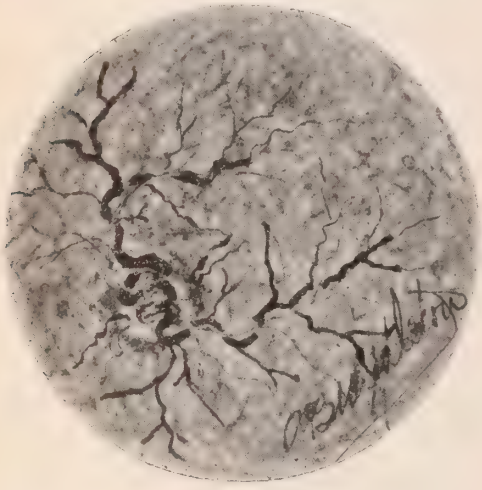

Fig. 2. Congenital varicose vessels of left disc.

dimness of vision. Denies specific history. No blindness or poor eyes in family. No history of a blow to the eye.

Examination. No squint. Tension normal. Vision O. D. 20/30; O. S. 3/200. Left cornea clear and free from scars. Anterior chamber deep; aqueous clear. Iris free from adhesions and deposit of pigment. Lens normal. Vitreous clear and not fluid. Vessels normal. Disc normal in size and shape. At the macular region there is a densely pigmented circular area three-fourths the disc diameter in width. The surface of the area is smooth, but mottled with very small whitish streaks one half millimeter each in width. The white streaks are not exudative but simply unpigmented retina showing between the heavily pigmented portion. Branches of the retinal vessels extending to the margin of the pigmented area, pass over the pigment. Large central scotoma. Pupil reacts to light and accommodation slowly. Power of convergence normal. No choroiditis or rupture of the choroid. No pigment deposits other than the area at the macula. See Plate VIII.

Case 7. Binocular Macular Hole in the Retina, Congenital Private L. A., (Col.) May 9th, 1918. Denies specific history. No mental symptoms present. No history of mental disease in the family. No history of having had a severe blow to the eyes or over the head. Weak eyes all of life, never had them fitted with glasses or examined by a doctor. One eye has always been as good as the other, neither one having given the slightest pain or discomfort other than the dullness in vision.

Examination. Tension normal. Vision O. D. 20/70. O. S. 20/200. Cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from adhesions and pigment deposit. Pupils equal in size but slightly dilated reacting slowly to light and accommodation. Power of convergence reduced. Disc normal in size and color. Vessels normal. No rupture of the choroid or choroiditis. At the macular region of each retina is a slightly depressed symmetric circular area, the diameter of which is one third the diameter of the disc. The exposed choroid at the bottom of the hole is a dark mahogany red, color more or less mottled with a slight pigment deposit. The margin of the retinal hole is slightly pigmented giving the appearance of a faint halo. Small central scotoma in each eye. No white exudative specks which are usually present in cases of traumatic retinal hole, the result of hemorrhage at the time of accident.

Case 8. Congenital Opaque Tissue on Disc. Private A. P. E., May 2, 1918. Right eye has been weak all his life, but has not given one moment's trouble other than the dimness of vision. No specific history, or history of poor

vision in other members of family. No severe blow to the eye.

Examination. No squint. Tension normal. Fields not taken. Vision O. D. 6/200; O. S. 20/20. Right cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from adhesions and pigment deposit. Lens normal. Vitreous clear and not fluid. Vessels normal. No choroiditis or choroidal rupture. Macular region normal. Disc normal in size and color, but on the nasal side of the disc between the forks of the retinal vein as it passes over the disc is a white circular spot, slightly elevated, two millimeters (apparent size of image) in diameter. No deposit of pigment or signs present to indicate that this might be an exudate.. The elevated area is due to opaque white tissue confined to the disc, this case being one of those that represents a white blackberry appearance of the disc when the elevations are multiple. Left disc normal. Vascular system is not disturbed at the site of the white spot. Disc not bulging in appearance, which is the case where the spots are multiple. No opaque nerve fibers in the fundus.

Case 9. Binocular Pigmentation of Fovea Centralis. Private R. R. (Col.) May 15, 1918. Farmer; single; aged 24 years; had weak eyes all his life, one eye not much better than the other. Never went to school or had eyes examined by a doctor before entering army. Denies specific history. No trauma.

Examination. No squint. Tension normal; vision O. D. 20/200; O. S. 20/200. Cornea clear and free from scars. Anterior chamber deep and aqueous clear. Iris free from adhesions and pigment deposits. Pupils slightly dilated but equal in size reacting slowly to light and accommodation. Power of convergence normal. Vitreous clear and not fluid. Lens normal. Vessels normal but the fundus is not as deeply pigmented as is the rule with colored people. Field shows a large symmetric central scotoma in each eye. In the macular region in each eye, directly at the fovea centralis is a densely deposited pigmented spot, circular, one millimeter in diameter (apparent size on fundus image) surrounded with light halo one millimeter in width. Disc normal in size and color.

Case 10. Bands Extending Across Physiologic Cup. Private B. F. B. July 1, 1918. Right eye has been weaker than the left all his life, but has never given one moment's trouble, and has not been examined by a doctor before entering the army. Denies specific history; no history of trauma.

Examination. No squint. Tension normal. Vision O. D. 1/200; O. S. 20/20. Right cornea clear and free from

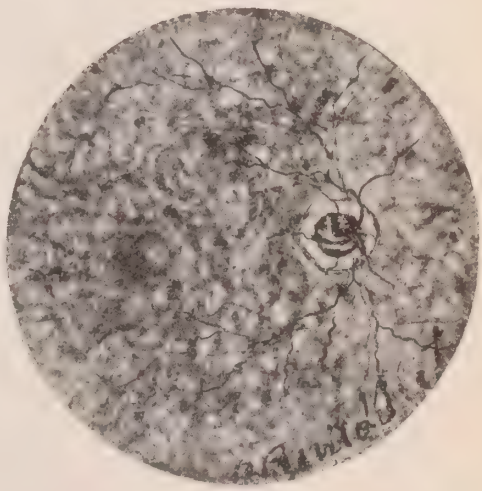

Fig. 3. Bands extending across physiologic cup.

scars. Anterior chamber deep and aqueous clear. Iris free from adhesion and deposit of pigment. Lens normal. Vitreous clear and not fluid. Vessels normal in size and location. Macular region normal with a bright foveal reflex. Disc normal in size and color with a large deep physiologic cup. Horizontally across the cup are two suturelike bands resembling silk worm gut. The upper band is bifurcated at the temporal end, the bifurcation extending upward to the side of the cup. These bands are given off below the exit of the central retinal vessels and are on a level with the disc. The normal lamina cribosa fibers can be seen plainly in the bottom of the physiologic cup. Field of vision not

taken. Left eye normal. See Fig. 3.

Case 11. Fold in the Retina. Private M. P. (Mex.), June 26, 1918. Denies specific history; has not had a blow to eye. Right eye has been weaker than the left all his life, but never had it examined or treated by a doctor. The eye has not given the slightest trouble other than reduced vision.

Examination. No squint; tension normal; cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from adhesions and deposit of pigment. Lens normal. Vitreous clear and not fluid. Vessels normal in shape and position. Disc normal in size and color. At the macular region there is a circular area of granular choroiditis of a dark red color one half the disc diameter in width. In the granular area are many small pigment specks one millimeter each in diameter giving a mottled appearance. Above the center of the macula are two densely pigmented circular spots two millimeters (apparent size) each in diameter, on the same level horizontally, three millimeters apart with no evidence of exudate. On the nasal side of the disc is a distinct fold in the retina, two millimeters (apparent) from the margin of the disc and two millimeters wide extending vertically toward and parallel with the nasal margin of the disc. The fold is a light gray color, free from pigment deposit along its margins, which is present in most cases of choroidal rupture. The retinal vessels leaving the nasal side of the disc pass over the retinal fold at right angles bending forward as they pass across the folded retina. No rupture of the choroid. No deposit of pigment or signs of hemorrhage at the site of the fold. Field of vision not taken. See Plate VIII.

Case 12. Dermoid Cyst of the Limbus. Private R. H. July 5, 1918. No tuberculosis in family. No history of trauma. Since childhood has noticed a round pinkish growth on the left eye, never painful or inflamed. Eye has not given one moment's trouble other than reduction of vision. No members of the family afflicted in this way. All have good eyes. No specific history.

Examination. Vision O. D. 20/40; O. S. 20/20. Tension normal; no squint; left cornea exposed, clear and free from scars. Anterior chamber deep. Aqueous clear. Pupil semidilated and kidney shaped, reacting to light and accommodation, but slow in convergence. Iris blue, free from adhesions and pigment deposit. Lens normal. Vitreous clear and not fluid. Disc normal in shape and color. Vessels normal. Macular region normal. On the nasal side of the cornea about "3:30 o'clock," on the limbus and slightly beyond the

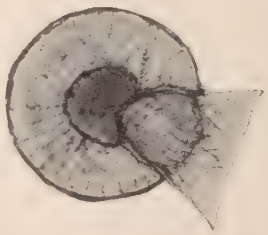

Fig. 4. Dermoid cyst of limbus (congenital).

pupillary margin is a circular, soft, movable tumor, one-fourth inch in diameter, of a pinkish gray color. The tumor is soft, giving the sensation under touch of hairs or varicose veins within the mass. No hairs growing from the surface. A band at the scleral margin of the tumor extends toward the outer canthus resembling a wide, thin pterygium. Many small vessels in the mucosa covering the tumor. Around the tumor in the cornea is a light colored halo. The tumor is freely movable but has a broad base and is six millimeters in thickness, which prevents the lids closing on the temporal side. Field not taken. See Fig. 4.

Case 13. Complete Pupillary Membrane. Private, J. R. M. May, 1918. No specific history. No eye trouble other than the slight dimness of vision in right eye. No tuberculosis in family. No history of trauma. All members of family have good eyes. Has not had eyes examined by a doctor before entering army.

Examination. Vision O. D. 20/20; O. S. 20/30. Tension normal. No squint.

Brown eyes. Cornea clear and free from scars. Anterior chamber deep. Pupil normal size. Iris free from adhesions or deposits of pigment, but there is a thin congenital filmlike membrane, covering the whole right pupil area, attached to the iris equally around the whole margin of the pupil. The membrane is nearly transparent. Examination with the loupe is required, which shows a vertical slit extending from one side of the pupil to the other resembling a cat's eye. The slit is two mm. wide at the center, gradually coming together at each end near the margin of the pupil. Atropin dilated the pupil slightly in the horizontal direction, but not vertically. The opening in the pupillary membrane separated equal to twice its original width under a mydriatic. The distant vision is reduced under atropin to O. D. 20/200. The left pupil is free from membrane or pupillary bands. No signs of inflammation or choroiditis in either eye.

Case 14. Ectasia of Sclera. Private J. L., (Col.), July 18, 1918. Specific history two years; has been blind in the right eye all his life, but it has never given the slightest trouble except the dimness of vision. The eye has never been hit a hard blow; or been red and inflamed. An external strabismus of twenty degrees present that has existed since childhood.

Examination. Vision O. D. 1/200; O. S. 20/20. Tension normal. External squint 20 degrees. Right cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from pigment deposit and adhesions. Pupil dilated, reacting slightly to light, but not to accommodation. No power of convergence. Lens normal. Vitreous clear and not fluid. Disc normal in shape and color. Vessels normal. Field not taken, power of vision too low. Below the macular area in the right eye is an elliptical shaped depression in the sclera three diopters deep. The hole is one and one-half disc diameter in length, and three-fourths of one disc diameter in width. The axis of the ellipse is up and in, toward the disc, at about the angle of eight o'clock. The retina dips down into and covers the bottom of the scleral opening, which is larger at the bottom than at the opening through the choroid. The retinal vessels pass down over the edge of the sclera into the scleral ectasia, disappearing the same as in the case of a glaucoma cup, appearing again, crossing the bottom of the hole making the same turns in their exit. Many small retinal vessels pass down over the margin of the hole, which is not sharp cut but rounded. There is no choroid in the depression, the choroid is very thin over the margin of the hole. The retina is considerably pigmented over the floor of the hole, but is not pigmented over the balance of the fundus. The temporal end of the hole contains a deposit of exudate and two deeply pigmented spots resembling apple seeds. Over them, extending from above, is a fanlike exudate covered with blood vessels. The handle end of the fan extends down into the hole, between the two apple-seed-like pigment deposits, attaching itself to the floor. The exudate and pigment deposit in the temporal end of the hole is the result of a specific choroiditis that has taken place in the congenital opening in the sclera. See Plate VIII.

Case 15. Dermoid Cyst Limbus of Cornea. Private B. S. Dec. 7, 1918. Age 25 years; farmer; single; has had a small pink lump on the right eyeball all of his life. Never has given the slightest trouble. The sight is as good in one eye as is the other. No history of injury to the eye. Each member of his family has good eyes, and no growths upon them.

Examination. Vision O. D. 20/20; O. S. 20/20. Tension normal. No squint. Brown eyes. Exposed portion of right cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Pupil kidney shaped, reacting to light and accommodation. Power of convergence normal. Iris free from adhesions and pigment deposit; lens normal. Vitreous clear and not fluid. Vessels normal. Macular region normal. Disc normal in size and color. No choroiditis or rupture of the choroid.

Field of vision not taken. At about "7 o'clock" on the limbus of the cornea is a light pinkish circular growth, three-sixteenths of one inch in diameter resting upon the cornea. Around this growth is a white halo resembling an advanced arcus senilis. The margin of the pupil appears to be displaced inward opposite the growth. The tumor is soft, no hairs growing from its surface. The broad base gives the appearance of being deeply attached to the cornea. The mucosa or conjunctiva over the growth is filled with many small vessels. Extending from the outer margin to the bulbar conjunctiva the growth spreads out into a wide band, like a thin pterygium. The eyelids close perfectly. No signs of a growth

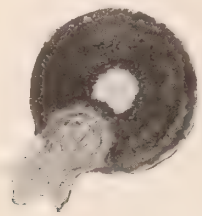

Fig. 5. Dermoid cyst limbus of right cornea.

on the left eyeball. Not painful and never inflamed. See Fig. 5.

Case 16. Fuchs' Coloboma. Private B. E. S. May 3, 1918. Has never been able to see as well with the right eye as the left. The eye has never given a moment's trouble and never had it examined by a doctor. Never had a severe blow to the right or any kind of inflammation.

Examination. Tension normal. No squint. Vision O. D. 20/200; O. S. 20/50. Right cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from adhesions and pigment deposit. Pupil normal in size, reacting to light and accommodation. Power of convergence normal. Vitreous clear and not fluid. Lens normal. Vessels normal. Macular region normal. Disc normal in color and shape, but directly below the disc is a crescentic coloboma of the choroid, slight yellow color and slightly depressed. The inferior retinal vessels pass over it, making a slight dip in their transit. No pigment deposit. No choroiditis or rupture of the choroid.

Case 17. Pigmented Scleral Nevus. Private C. T., July, 1918. Mexican; age 30 years; farmer; married; does not speak English. Interpreter states that soldier claims the black spot on the white of his right eye has been there all of his life, but is not painful and never has been inflamed or sore. No history of injury or severe blow to the eye. The eye has always been blind, never consulted a doctor with regard to the eye. General health good, works hard every day, has not lost any weight. No member of the family afflicted in this manner. No specific history. No tuberculosis in the family.

Examination. No squint. Tension normal. Right cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Iris free from adhesions and deposits of pigment. Brown eye. Pupil normal in size, reacting slowly to light but not to accommodation. Power of convergence sluggish. Lens normal. Vitreous clear and not fluid. Vessels and disc normal in size and color. No choroiditis, or rupture of the choroid. Fundus dark and deeply pigmented, a condition that is often present in normal Mexican eyes. Left eye normal. Between lids of the right eye opposite the outer half of the palpebral fissure, on the surface of the sclera is a triangular pigmented area. The base of the triangle is at the limbus of the cornea, the apex extending to the temporal end of the palpebral fissure. The base of the triangle is three-eighths of one inch wide, one-half inch in length. The pigmented area is a dark brown color and not elevated or nodular. No disturbance of the vascular system over or near this area. The bulbar mucosa is elastic and not adherent over the nevus. The deposit is confined to the surface of the outer layers of the sclera. The base of the triangle extends beyond the limbus into the corneal tissue two millimeters. The choroid and retina opposite the pigmented area are normal. The pupils dilated equally with atropin.

Case 18. Retinitis Pigmentosa. Private H. B. F. History. "Have had good eyes all my life but cannot see as well after dark as other people, in fact can't get around without feeling my way with a stick. Several in family have weak eyes, but I don't know what is wrong with their eyes. I am the only one that cannot see after dark. Have had my eyes examined by eye doctors and told that I have night blindness. Father and mother not related; no intermarriage among ancestors." No specific or tubercular history.

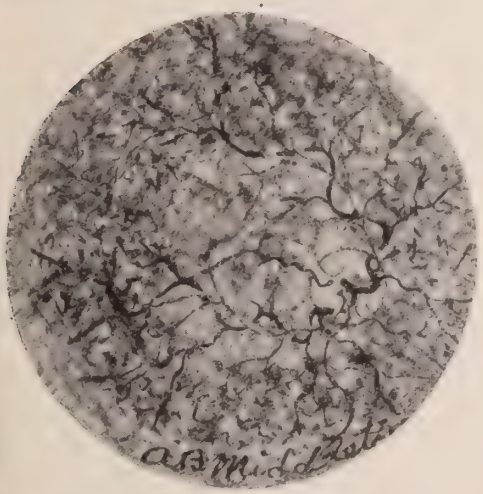

Fig. 6. Retinitis pigmentosa.

Examination. Age 22 years; single; farmer; vision O. D. 20/15; O. S. 20/20. No squint; tension normal; cornea of each eye clear and free from scars. Anterior chamber deep. Aqueous clear. Lens normal. Iris free from adhesions and pigment deposits. Vitreous clear and not fluid. Vessels and discs normal in shape and color. No choroiditis or rupture of the choroid. Pupils normal, reacting to light and accommodation. Power of convergence perfect. Field of vision shows the usual typical field found in cases of retinitis pigmentosa. On the surface of the choroid is a pigmented band completely surrounding the fundus, the extreme outer margin of the fundus being clear and free from pigment deposit. The pigment deposit is spindle shaped, several spindles in a cluster located in the anterior layers of the retina, the retinal vessels passing under the pigment deposits. Fig. 6.

Case 19. Coloboma of the Lens. Private J. K. S. Has had weak eyes all his life; age 25 years; carpenter; married; eyes have never given the slightest trouble other than the reduced vision. Father living; good sight. Mother 58 years old, had a painful trouble with eyes for many years. The last seven years has been obliged to feel her way about the room. Three brothers all have good sight; one sister, age 35 years, has weak eyes; one sister died of appendicitis at the age of 16 years, had weak eyes; one sister has two children, one girl good eyes, one boy E. H., 11 years old, in the blind school, Austin, Texas. Mother's brothers and sisters have good eyesight.

Examination. No squint; tension normal. Vision O. D. 20/50; O. S. 20/20. Both corneas clear and free from scars. Anterior chambers deep. Aqueous clear. Pupils normal in size, reacting to light and accommodation. Power of convergence normal. Iris free from adhesions and pigment deposits, but tremulous, the right much more than the left. Vitreous clear and not fluid. Vessels normal. Disc normal in size and color. No choroiditis. No coloboma or rupture of the choroid. No coloboma of the ciliary body, iris, or retina. Right lens shows two coloboma notches on its lower margin. The larger notch at the position of "four o'clock," is a perfect semicircle, the apex extending four millimeters toward the center of the lens the base of the semicircle six millimeters broad. A second coloboma notch at the position of "six o'clock," also a semicircle, but smaller, extending three millimeters toward the center of the lens with a base of four millimeters. The colobomas are separated by a strip of clear lens two millimeters in width. The left lens has two incomplete colobomas which are nothing more than slight depressions in the lower margin of the lens. Lenses do not im-

prove vision. Field of vision not taken.

Case 20. Fuchs' Coloboma Binocular. Private B. E. S., May 3, 1918. Eyes have been weak all life, the right weaker than the left. Soldier, illiterate, never had eyes examined by a doctor before entering the Army. No specific history or history of tuberculosis. Eyes never pain or become inflamed. No weak eyes in family. Suffers considerably with headaches, the main reason for not attending school, which increased the severity of the attacks.

Examination. Farmer; 23 years old, single; no squint. Tension normal. Cornea of each eye clear and free from scars. Anterior chamber deep; aqueous clear. Pupils normal in size, reacting to light and accommodation. Power of convergence reduced. Iris free from adhesions and deposit of pigment. Lens normal. Vitreous clear and not fluid. Vessels normal in size and color. Each fundus has a coloboma of the choroid four millimeters (apparent) in width directly below, and connecting with the disc. Field of vision not taken. Retinoscopy under a mydriatic: Horizontal —3, vertical 0, in each eye. Corrected with +3 cylinder axis 90 gives 20/40 vision in each eye.

Case 21. Monocular Guttate Choroiditis. Private L. A. L., April 30, 1918.

Has not seen well out of left eye, and it has been crossed all his life. The eye has not given one moment's trouble other than poor vision. All the members of family have good eyes; the patient only one that is cross eyed. No history of severe blow to the eye.

Examination. Left internal strabismus 25 degrees. Tension normal. Farmer. No specific or tubercular history. Age 22 years; vision O. D. 20/20; O. S. 1/200. Retinoscopy right horizontal +3, vertical +3. Left horizontal +2, vertical +2. Left cornea clear and free from scars. Anterior chamber deep. Pupil dilated slightly, reacting slowly to light and accommodation. Iris free from adhesions and pigment deposit. Vessels normal. No choroiditis or rupture of the choroid. Disc normal in size and color. At the macular region is a circular cluster of guttate choroiditis dots, seven in number, "two millimeters" each (apparent), in diameter, of a yellowish gray color, arranged in a wheel shape, the diameter of which is ten millimeters; one dot acts as the hub and is directly over the fovea centralis. The right fundus is free from guttate choroiditis. Field of vision shows a large central scotoma. Cannot rotate eye outward beyond the central line. See Fig. 7.

Case 22. Binocular Guttate Choroiditis. Private J. A. R., May 1, 1918.

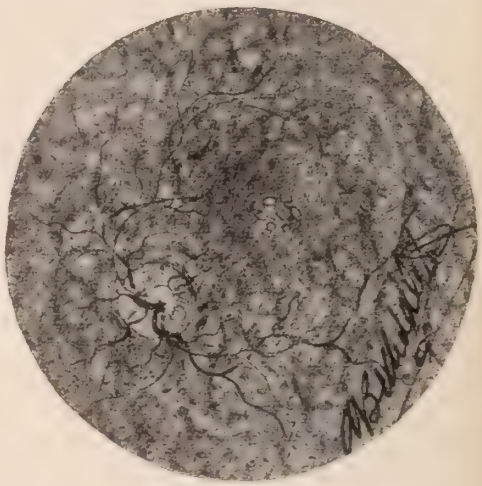

Fig. 7. - Monocular Guttate Choroiditis.

No specific or tubercular history. Vision has been poor in both eyes all his life; but never had them examined or fitted with glasses. Eyes have not given one moment's trouble other than dimness of vision. Several members of the family have weak eyes, the cause not known.

Examination. Farmer; age 24 years; vision O. D. 5/200; O. S. 20/20. No squint. Tension normal. Cornea clear and free from scars. Anterior chamber deep and aqueous clear. Pupils larger than normal but equal, responding to light and accommodation. Power of convergence normal. Iris free from adhesions and pigment deposit. Vitreous clear and not fluid. Vessels normal. Discs normal in size and shape but both have a dirty gray color. At the

macular region is a cluster of grayish white choroiditic dots free from pigment deposit. The dots are two millimeters each in diameter, the cluster is circular and made up of fourteen. This area is equal in size to the disc. The center of the circle is over the fovea centralis. The fundus of each eye is a near duplicate. No rupture of the choroid or choroiditis other than the dots at the macula. Central scotoma each field of vision.

Case 23. Guttate Choroiditis Bilateral. Private C. W. H., April 29, 1918. No specific or tubercular history in family. Never received a severe blow to either eye. Vision has been poor in the right eye all his life, but never consulted a doctor with regard to eyes. Many in the family have weak eyes, but the cause is unknown.

Examination. No squint. Tension normal. Vision O. D. 15/200; O. S. 20/25. Retinoscopy, right horizontal +4. Vertical +4. Left +1. Horizontal +1. Farmer; 23 years old; single. Guttate dots found in each fundus which are near duplicates. Cornea clear and free from scars. Anterior chamber deep. Aqueous clear. Pupils normal and equal, reacting to light and accommodation. Power of convergence slow. Lens normal. Vitreous clear and not fluid. Discs normal in size and color. Vessels normal. No rupture of the choroid or choroiditis except the circular cluster of guttate dots at the macular region of each fundus. The center of the circle is directly over the fovea centralis; this circle is made up of eleven grayish yellow dots "two millimeters" each in diameter, not pigmented and covering an area equal in size to the surface of the disc. The dots are smooth, located in the choroid. Field of vision not taken.

Case 24. Guttate Choroiditis Bilateral. Private W. R. B., May 3, 1918. No specific or tubercular history in the family. No history of severe trauma. All members of family have good eyes. Vision poor in left eye all his life. The eye has not given trouble other than the reduced vision. Has not had the eye examined by a doctor before entering the service.

Examination. No squint or increased tension. Cornea of each eye clear and free from scars. Anterior chambers deep and aqueous clear. Left pupil slightly dilated, reacting to light and accommodation slowly. Power of convergence reduced. Iris free from adhesions and pigment deposits. Lens normal. Vitreous clear and not fluid. Vessels normal. Discs normal in shape and color. No rupture of the choroid or choroiditis except a circular area of guttate choroiditis in the macular region. The area of guttate dots is covered with about twenty-five smooth yellowish gray dots, "two millimeters" each in diameter, nonpigmented. The center of this area is directly over the fovea centralis and covers a space about the size of the disc. Field of vision not taken. Fundus picture the same in each eye.

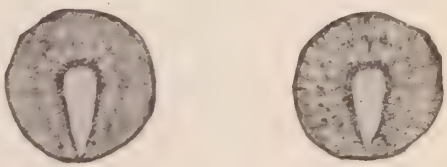

Fig. 8. Binocular coloboma of iris.

Case 25. Binocular Coloboma of Iris. Private J. G., May, 1918. Mother claims that he had "cat's eyes" all his life, due to a scare that she had just before his birth. None in the family have anything of this kind. Parents were not of the same family. Eyes have not given any trouble except poor vision and people stare at them all the time. No history of trauma.

Examination. No squint. No specific or tubercular history. Tension normal. Cornea clear and free from scars. Anterior chamber shallow. Aqueous clear. Pupil of each eye keyhole in shape with the slot downward, the bottom of the sides coming together at the limbus. Iris blue, free from adhesions and pigment deposit. Pupil reacts slowly to light and accommodation. Power of convergence normal. Vision O. D. 20/40; O. S. 20/40. Vitreous clear and not fluid. Vessels and discs normal in size, shape and color. No

coloboma of the choroid, ciliary body, retina or lens. Pupil dilates slightly in all directions with homatropin. Fields of vision not taken. See Fig. 8.

Case 26. Monocular Microphthalmia. Private J. T. (Mex.), August, 1918. Right eye has always been blind and much smaller than the left. Vision in left eye 20/20; right eye has not given any trouble other than the blindness and appearance. Never had any inflammation or a severe blow to the right eye.

Examination. Mexican. Does not speak English; information gained through an interpreter. Right eyeball one-third smaller than the left. Cornea five millimeters in diameter, but clear and free from scars. Anterior chamber shallow, filled with clear aqueous. Iris very narrow, not responding to light. Homatropin produced slight dilatation. Lens clear. Not able to determine fundus condition. Vitreous not clear enough to see the disk or fundus. All motor muscles normal. No squint. No tension. No specific or tubercular history. None of the family troubled in

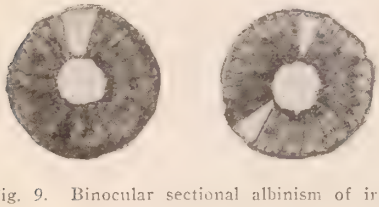

Fig. 9. Binocular sectional albinism of iris.

this manner. Parents not relatives. Farmer, 26 years old; married; children normal eyes.

Case 27. Binocular Sectional Albinism of Iris. Private E. J. (Col.), May, 1918. No specific history. Had white sections in the brown part of eyes all his life. Eyes never painful or become inflamed. Has not had them examined by a doctor. None in the family afflicted this way. No albinos in the family. Cannot stand light without squinting the eyes. Vision always poor in the left eye. No history of injury or tuberculosis.

Examination. Farmer; single; age 23 years; vision O. D. 20/20; O. S. 20/200. Tension normal. No squint. Cornea clear and free from scars. Anterior chambers deep and aqueous clear. Lens normal. Pupils normal and equal, reacting to light and accommodation. Power of convergence sluggish. Iris free from adhesions and deposit of pigment. In the iris of the right eye, which is a dark brown, is a white transparent sector six millimeters wide including the entire width of the iris at the angle of "eleven forty-five o'clock." Through the transparent sector it is possible to see the fundus and the outline of the lens with slight difficulty. With the exception of the one nonpigmented sector the remainder of the iris is one shade, and normal in color. The left iris has two nonpigmented sectors, three millimeters each in width, extending thru the entire width of the iris. One of the sectors in the left iris is at "two o'clock" and the other at "six," they are white and transparent, the same as the sector in the right eye. The pupils dilate easily and equally under atropin. The refraction is normal in each eye. Soldier squints with eyes all the time to avoid the light. Vitreous clear and not fluid. Vessels normal in shape and color. Disc normal. No choroiditis or rupture of the choroid. No coloboma of the choroid, ciliary body, iris, or lens. Fields of vision not taken. See Fig. 9.

CLINICAL OBSERVATIONS IN THE OPHTHALMIC SERVICE AT CAMP SEVIER, S. C.

MAJOR WARREN E. KERSHNER, M. C.

BATH, MAINE.

This account of the ocular conditions encountered in such a service is published under authority to publish granted by the Board of Publication, S. G. O.

The class of cases seen in the ophthalmic service of an army base hospital is somewhat different from the cases observed in civil eye clinics. The range of cases is more limited for two reasons: first, the ages of the patients are nearly alike, or have been during the period covered by this study, second, similar or nearly similar environment of the men narrows the field of possible ocular conditions.

From January 1, 1918, to November 1, 1918, the new cases admitted to the clinic for treatment have numbered 1953 or just under two hundred new cases per month. This does not include the many visits for routine vision testing, a part of physical examinations, nor does it include the officers, their families, nor members of the Army Nurse Corps, the records of whom are kept in a separate class for reasons of age, sex, living conditions, etc.

It may be of interest to speak of the refractive work. It indicates the number of young men who go without proper refractive work or who are not constant in wearing their correction. Many such were found, numbering very nearly fifty per cent of those applying for correction of refractive errors. The histories of these patients also demonstrate that excessive near work may not be the chief factor in sending the young hyperope to the ophthalmic surgeon. By far the majority of these cases came complaining of the effect of the wind and especially the sunlight upon the eyes. A proper refraction relieved the symptoms complained of. A study of the refractive work of all the camps will give us the refractive index of the young male American as a class. We did at Camp Sevier 839 refractions of all kinds. About fifty per cent of these had been refracted previously and slightly over ten per cent were still wearing their corrections. All refractive work was done under atropin or homatropin. Retinoscopic and ophthalmoscopic refractions were estimated in all cases and thoro going trial case work was done. The results were as follows:

14% accepted plus spheres
03% accepted minus spheres
10% accepted plus cylinders
03% accepted minus cylinders
53% accepted plus spheres and plus cylinders
06% accepted minus spheres and minus cylinders
11% accepted plus spheres and minus cylinders or minus spheres and plus cylinders.

It should be noted as well that very nearly thirty per cent of the refractive errors showed also an anisometropia of 0.75 D. or over.

CONJUNCTIVITIS. There have been 741 cases of acute conjunctivitis treated at this clinic. These include nearly four hundred cases treated, which were classed as epidemic. But this socalled epidemic coexisted with one of mumps and measles.

In the whole series the pneumococcus was the offending organism in a large percentage of cases. On the whole the findings from a bacteriologic standpoint are not materially different from the series reported by the author in the July number of the American Journal of Ophthalmology, page 480, except a slightly higher pneumococcus percentage, a lower number in which no organism was found, and double the percentage of Koch-Weeks infections.

The conjunctival diseases include, besides some chronic cases, eight cases of self-imposed traumatic reaction and two marked cases of vernal catarrh. In

one of the latter the hyperplasia of the conjunctiva entirely encircled the cornea and presented a decided elevation with a width of two to three millimeters.

Phlyctenular conjunctivitis was seen seven times, with an additional case which invaded the cornea.

Trachoma. Sixteen cases of trachoma have passed through our hands. By permission of the commanding officer we were allowed to keep cases of this disease in the hospital under proper regulation in order to carry out treatment. The so-called Bacillus bulgaricus treatment was tried thoroly in seven cases of chronic or quiet trachoma and upon two cases of the active type. Of the acute cases, both were seen when there was marked congestion, injection, pain and discharge. Pannus was marked in both cases. The treatment increased every symptom to such an extent that this method of treatment had to be discontinued. The cases were then treated with copper stick until the active symptoms subsided and the pannus disappeared when a shift was made to the Bacillus bulgaricus. Again every symptom increased, requiring discontinuance once more. The tablets used were fresh, kept in a cool place and powdered daily. The plan of treatment in these, as well as in the chronic cases, was that described by Crawford, in his paper read before the Nashville Academy, May 16, 1916, entitled "Fourteen Cases of Trachoma or Granular Lids treated with Bacillus bulgaricus" and an article by the same author in the Annals of Ophthalmology of October, 1917, Vol. XXVI., No. 4, page 557. As implied, the treatment in acute cases was not satisfactory, quite the contrary, for the injection and edema increased, the discharge increased, the pain and discomfort were worse and the pannus enlarged under this medication. The treatment simply had to be abandoned after all the trial safety would allow. The seven chronic granular cases were under treatment from three to four months with the freshly powdered tablets. In no case did we see active excitation of the disease after or during treatment. The treatment was not unpleasant to the patients but that is as far as it goes. In no case was improvement seen either before or after manual expression of the granules. In two additional cases the diagnosis of which was doubtful at first, but which were held under observation, we found some slight temporary improvement during the quiet and restriction of the observation and treatment period. Upon return to the wind, smoke, sun and dust of their active army life these cases quickly relapsed. As a result of these few cases treated and studied it is safe to state that there is no field for this treatment in the army. The cases which showed any improvement in our hands have been small. The improvement is temporary. Even if the results were better the time required is too long to be of practical value in the army. The treatment is detrimental to acute cases. As a result of the experience at Camp Sevier, it is believed that the treatment has no influence upon the trachoma.

Conjunctival Conditions. One of the striking conditions constantly met with in great numbers in these young men was pinguecula and pterygium. That age is no barrier to these two conditions in the south and middle southwest was manifest at this clinic. It was seldom that these patients came to the hospital for the manifest condition. On the contrary they came for refractive errors.

Two patients were seen here who presented a rather rare condition, namely blood channels of the conjunctiva. One was a decided blond, the other just as positively a brunet. The history in both cases was unimportant especially in that there had been no history of injury, no foreign body nor other conjunctival change. These "vessels" have been present in one case for a year and in the other for a year and a half. With the channels were also present enlarged veins which were tortuous. Adrenalin was used to get the effect and to demonstrate whether or not there was active injection present. The drug contracted the vessels but not the channels. A section of the

conjunctiva was removed in both cases and submitted to the laboratory for examination and report. The reports were similar and to the effect that the specimen presented vessels with only endothelial cells as vessel walls together with apparently enlarged vessels of normal structure. The normal as well as the abnormal vessels both lay deep and superficial in the conjunctival tissue. In places the channels showed the lumen as flattened septa-like slits lined with the same endothelium cells between these and fibrous tissue. These cases were similar to the section exhibited by Lang at the Royal London Ophthalmic Hospital on April 27, 1905, as reported in the American Encyclopedia of Ophthalmology, Vol. IV, page 3073.

There has probably been less gonorrheal conjunctivitis in the army than one would expect. Our cases numbered five. Each was correctly diagnosed by the virulent symptoms. The laboratory confirmed the character of the infection by smear and culture in each instance. The treatment employed was as follows: continual cold packs, silver nitrate 2% once daily, flushing of the eye every twenty minutes night and day with boric acid, saturated solution, with argyrol used as a float every hour, protection of the unaffected eye, light diet, continual rest in bed and attention to the bowels. Under the above treatment all cases were germ-free in a week and ready for duty soon after. In no case did the infection reach the sound eye. No complications were present upon the first visit nor developed after treatment began.

Hordeolum and chalazion were common. Nothing of interest occurred in connection with the lid cases.

One case of long standing symblepharon came for treatment because of the irritation and discomfort produced by exposure to the wind and dust of the outdoor life. The adhesion was complete, of the lower lid, the external two-thirds. The attachment was at the corneo-scleral junction and directly outward to the outer canthus. Conjunctival flaps were brought down from above. The flaps healed in place readily, producing a very satisfactory result. The patient went to France with his organization free from symptoms.

Strabismus. There have been forty-one operations for strabismus to date. The majority came to the clinic for relief of the disfiguring effects. In some of these the opportunity to train the muscles after operation was short or did not exist.

The squint cases were classed as follows:

	Number
Strabismus convergens	(28)
Monocular	16
Alternating	12
Strabismus divergens	(11)
Monocular	3
Alternating	6
Secondary to tenotomy internal recti	2
Strabismus verticalis	(2)

All of the patients were between 19 and 25 years of age except one who was 31. The perimetric deviation was from 30 to 55 degrees. In all cases the onset was before the sixth year of life. Glasses had been, or were being worn by but three cases. The glasses and the refractive status were of little practical value as only one was affected or benefited more than 5 degrees by glasses. Eleven of the convergent squint cases had evidently a "working" fusion faculty, as binocular single vision developed after operation. Seven of the divergent type also resulted in binocular single vision. One of the divergent group was converted from a constant alternating squint to one of the occasional type. In three cases of the convergent type a second operation was required in order to secure a satisfactory cosmetic result. In the first class the operation consisted of one of the muscle shortening operations with graduated tenotomy of the opposing muscle in twenty-five of the twenty-eight cases. In the three remaining cases of this group a shortening only was done.

All the divergent cases were operated by complete tenotomy of the external recti muscles. The vertical cases were treated by a graded tenotomy of the superior rectus muscle of the affected

side. Of the two patients with a divergent squint secondary to a tenotomy of the internal recti, one was of four years standing, the second of twelve. The first one presented a left eye, proptosed, with a wide palpebral fissure and limited internal rotation. The capsule of Tenon was opened. The rectus was found and was brought forward to or in advance of its normal position and attached by scleral sutures. The capsule above and below the muscle was advanced as well. In the second case double complete tenotomy of both internal recti had been done, which had resulted in a wide divergence. The operation in this case consisted of opening the capsule on both sides, finding the atrophied muscles and bringing them into proper position and, by scleral suture, fixing them there as indicated in the previous case. Both cases after four months were as follows: from a cosmetic standpoint straight eyes. In the second case we find 4° of exotropia for distance and 11° for near. The binocular single vision in the first case is not constant but up to the present has improved slowly. The excursions are limited in inward duction in both cases. There would seem at this time to be a fair degree of permanency and, considering the length of time the old tenotomized muscles have been out of use, the results are satisfactory.

Lacrimal Disease. Five patients have been operated for obstruction of the lacrimal duct with chronic dacryocystitis. Both sides were operated in three of the cases. Two patients, one with single and one with double obstruction, were treated by the trichloracetic acid method of Gifford. Three treatments by this method were all that were needed to be convincing that the method was out of place in the army. The time from duty was long in each instance. While the end results were all that could be expected the resulting scar was as marked as by extirpation and the extra time for the wound to fill up with granulation tissue made this method less satisfactory. All other cases were operated by extirpation. The end results have been satisfactory and all cases but one have been ready for duty in from five days to one week. The writer can see no comparison between the methods used here.

Corneal Disease. It should not be passed without comment that there have been no cases of ulcus serpens or interstitial keratitis seen at this clinic. Considering that the clinic has been the place of treatment for well up to a hundred thousand young men of all classes, the above statement seems remarkable.

Several cases of dendriform and simple ulcers were treated but require no remarks.

A very interesting and unusual case of disciform keratitis was under treatment. The onset and course was typical and uneventful at first. It was not possible to find a clue to the cause except a positive history of syphilis of six years' standing, but the laboratory findings were negative to the Wassermann reaction. At the height of the clinical course there appeared, opposite the central area on the posterior surface of the cornea, a perfectly pearl-white nodule, fixed and very small. The general reaction in the eye was not marked and there were no evidences of iris or uveal involvement; the iris remaining clear and mobile up to this point. On the fifth day after the appearance of the nodule the central area bulged forward slightly. Pressure was applied but the next day the cornea perforated and the anterior chamber emptied. The eye now began to be somewhat painful. From the first visit of this patient fluorescein was used daily but no abrasion of the corneal epithelium was found. Following the perforation of the cornea a very small tortuous sinus thro the cornea stained. It required magnification to see this well. This sinus remained open for four days even under pressure. At this time and following the closure the general reaction and pain were greater, and a mild low-grade iritis or iridocyclitis developed which gradually resolved as the corneal condition began to take on the characteristics of the more usual form of the disease. The terminal condition is

now what is to be expected from disciform keratitis, namely a permanent opacity, faded, with the discs less distinct. All the indications as described by Fuchs were present, the added element being the nodule on the posterior corneal surface and the perforation.

Injuries. One of the most unique of accidents was a discission of the lens by a safety pin. A soldier, who worked in the shoe repair shops, pulled a pair of shoes from a line. The shoes were fastened together by a safety pin. The pull opened the pin and it hit the eye with enough force to cause the following injury. The point entered the left eye at about 2 o'clock and 3mm. inside the corneoscleral junction, proceeding down and in. The point first hit the lens capsule 2 mm. below the center of the lens, then the lid action in closing applied the force to the long arm of the lever which brought the point of the pin almost directly up, opening the anterior lens capsule for fully 3 mm. Swelling of the lens was prompt and so pronounced that it was followed by a rise in tension. Linear extraction was done. The eye at no time suffered more reaction than if a sterile instrument had entered the globe.

Another case of contusion of the globe was followed by a severe hemorrhage into the anterior chamber, with blocking of the filtration angle and an increase in tension. This was evacuated by opening the anterior chamber and was followed by a second collection of blood which had to be evacuated a second time. There was no injury to the posterior segment of the eye, there was no detachment or tearing of the iris tissue which could be discovered, and the lens was intact.

Miscellaneous. The close association and perfect *coördination between the different services* in a base hospital, especially the Head Section and X-Ray Laboratory, have made it possible to do thoro investigative work in the focal infection cases and place the ocular conditions where they belonged regarding their etiology. The operative work of the dental service deserves recognition for prompt and thoro-going abolition of dental defects which served as causes of ocular pathology. The nose and throat service has been thoro and active in eliminating sinus and nasopharyngeal foci. The cases of ocular disease traced to dental or nasopharyngeal foci of infection have been about evenly distributed between the reflex neuroses and active inflammatory processes. Sinus infections have produced the majority of the muscular and asthenopic symptoms while apical abscesses, tonsilar infection and active ethmoidal infection have caused the majority of the inflammatory changes in the ocular structure. In eleven cases of iritis or iridocyclitis abolition of abscessed tooth roots caused an immediate resolution in the eye symptoms. One case of active exudative choroiditis was traced to an extensive involvement of the ethmoid cells and frontal sinus. The cases of unstable muscle balance, asthenopia, blepharopasm and accommodative deficiency have been much harder to trace and place exactly. Service conditions demand that soldiers be returned to duty with as little loss of time as possible, therefore in these cases the different departments worked together and at the same time. Ocular equilibrium was established by nasal or throat treatment in seven cases after proper and thoro going refraction had failed to relieve the symptoms, and this without altering the refractive correction. The same is true in one case of tooth impaction. In no case did the operative work on the teeth or nose and throat cause an increase in the ocular symptoms.

A summary of the *syphilitic conditions* of the eyes is being made by Captain James M. Blackwood, M. C. The end results in these cases have not been so satisfactory as they might have been. The cases affecting the uveal tract have presented the so-called quiet type and have progressed to a considerable extent before being seen by the ophthalmologist. Treatment of such cases is needed over a considerable period of time and observation over a much longer time still. The constitutional treatment of the syphilis seemed to give slow results in the cases of long

standing and it should be strongly emphasized that the ocular treatment should be just as active, thoro and vigorous as tho the general disease was not known. Especially must this be true for the reason that very active general treatment may increase the local reaction in the eye. There has been one such case here. This was in a late case where full doses of arsphenamine or one of the similar preparations was used. An immense amount of work must be done before the definite relationship of syphilis to eye diseases is placed on a stable foundation, especially the influence of general treatment and the type of constitutional treatment best suited to different phases of ocular pathology.

A considerable variety of *fundus lesions* have been seen. These may be classed for our purpose, into the active cases and the non-active or old cases. Of the active class there have been seven cases of optic neuritis, eleven of choroiditis, four of neuroretinitis, one of retrobulbar neuritis, two of hyalitis and two of choked disc. The old cases were more numerous and for the most part were seen in applicants for refractive corrections; simple optic atrophy seven, secondary optic atrophy five, pigmentary retinal degeneration six, familial optic atrophy four, central choroiditis eight, disseminated choroiditis six and rupture of retina one.

Malingering has been constantly present in one of its many classes or varieties. Much has been said and written on this subject, which has become a rather deep study at present. It seems to the writer that too much classification is confusing. He prefers to divide them into two main groups: The positive group which would include all cases who with intent, "manufacture" their condition or complaint without a basis or ground work for such a complaint, and this without respect to the mental or physical type of the malingerer. Then a negative class who often do have a ground upon which an exaggeration can be used to their advantage, or those who for fear do not fully realize that they are trying to evade duty. All such cases, of whichever type, must be treated as individuals. The author has found nothing short of wonderful the sight-restoring influence of treatment which is not pleasant or is more disagreeable than the "blindness," or "pain," or "neuralgia" or whatever they complain of. Therefore, in the second group especially and in some of the first group, silver nitrat, one or two per cent put into the conjunctival sac, without a local anesthetic, has worked like a charm. After three to six such applications the patients will usually and gladly demonstrate that they can see "lots better," or are less sensitive than when they applied for treatment. The cases are not a few in which the vision has improved (?) from 20/100 to 20/20 or 20/30 under such treatment.

A field which has been much neglected has been a study of the eye findings in the soldiers sent to the hospital for nervous and mental examination. Under the present orders to the effect that all men who seem unstable, hard to handle and excitable be sent to the psychiatrist, there has been a wide field of study of the eye conditions in these border-line cases. Such a study may have an important bearing on the early diagnosis of mental states, especially the functional psychoses. That this work has not been undertaken is due to the fact that there have not been ophthalmologists enough on duty here, to attend to the routine work of the eye department and find time for the extensive observation along these lines at the same time. This work has been recently undertaken and should yield valuable results.

TUBERCULOUS IRIDOKERATITIS—SOME FEATURES IN ITS PATHOLOGY.

CAPTAIN FRED T. TOOKE, C. A. M. C.

MONTREAL, CANADA.

This is a report of the histologic findings in four cases subjected to microscopic study, with comment upon the significance of the appearances observed. Read at the fifty-fourth annual meeting of the American Ophthalmological Society.

Iritis, perhaps more than any other form of ocular disease, has manifested a modification in its classification in comparatively recent years. Even including that evanescent issue, conjunctivitis and its bacteriology, no branch of the subject has made more actual advance than the study of iritis. The text-book of less than two decades ago taught that lues was responsible for 75 per cent of all patients suffering from iritis, and that so-called rheumatism, gonorrhea, tuberculosis, and trauma had to scramble for the balance.

The Wassermann reaction, the complement-fixation test, the careful examination of the sources of autogenous infection, teeth, tonsils, accessory nasal sinuses, and bowel, have modified the classification percentage of earlier days to a very appreciable degree. It is questionable if the figures of Hirschberg, who quotes 12 cases in 60,000, and Terson, 2 in 30,000 eye cases, would stand in the light of our present knowledge. The masterly work of de Schweinitz on uveitis, read before a recent International Ophthalmological Congress, would support such a challenge.

With a preconceived endeavor of exhibiting some of the tuberculous manifestations of the disease I have been peculiarly fortunate, during the past few years, in having material supplied me manifesting tuberculous processes in the iris with other associated features of the disease.

I would, at the outset, record my thanks to those of my colleagues who have by their contributions, made this paper possible.

The pathologic manifestations of this subsection of iritis are no less varied than the alterations of our point of view clinically and etiologically of iritis itself. The pathologic manifestations have naturally many features in common with other forms; on the other hand, each has its own peculiar or particular distinguishing feature.

CASE 1.—Material supplied by Dr. J. W. Stirling, Royal Victoria Hospital, Montreal.

Mrs. G., aged thirty-five years, married. Active, but poorly nourished, and with a marked family history of tuberculosis. A history of trauma of the right eye fifteen years earlier, the condition of inflammation requiring three months to subside. Present attack had been in progress for three weeks before she decided to consult Dr. Stirling. The cornea was steamy, or semi-opaque, the condition being more intense at certain segments, especially in the deeper tissues. Details of the iris could not be determined, and there was marked pericorneal injection.

There was a slight hypopyon but no acute pain. Later the hypopyon became more manifest, and the infiltration of the cornea more intense, with the presence of what appeared to be deposits on Descemet's membrane. There was a general rise of evening temperature to 99.2°; tension was low.

A paracentesis of the cornea was done, and a clot of organized exudate was removed from the anterior chamber without complication. Rapid progress followed this procedure, all signs of inflammation subsided, and in two days' time she was discharged from the hospital.

The specimen supplied resembled a particle of pus or slough. It was irregular in shape, of a yellowish-white color, and of a firm or solid consistence, not disintegrating when immersed in fluid. It measured approximately 6x2 mm. Sections were made in paraffin.

On examination by low power the section appears as a ribbon-like band, curved as though one side had been in contact with the inner surface of the cornea. It consists for the most part of two types of cells. The structure is of a network of new connective-tissue fibers, which are in fairly close apposition at one or two points, but at others the intercellular spaces are fairly well defined. The stroma of connective tissue is most dense anteriorly, bounding that part of the band the curvature of which would appear to conform to that of the adjacent cornea. Scattered through the stroma are quantities of white blood-cells which are distinctly more numerous as one proceeds backward (Fig 1.).

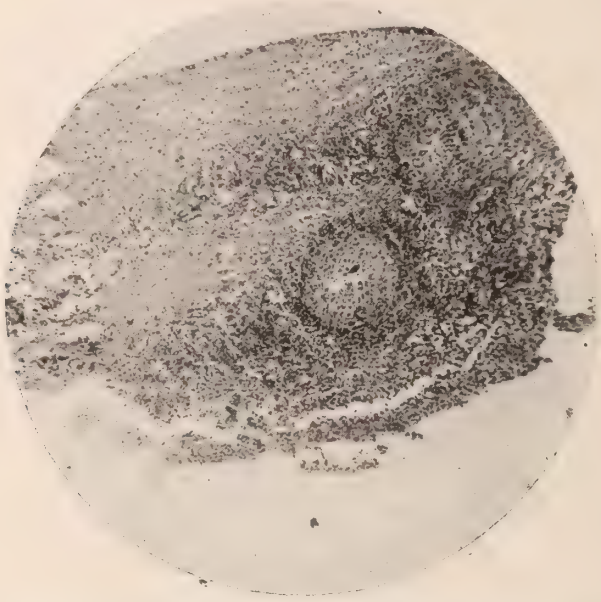

Fig. 1. Case I. Stroma of new connective tissue fibres most dense anteriorly. Scattered thru stroma are innumerable leukocytes and several tubercles best noted in posterior portion of the section (low power).

On examination by higher power one frequently observes that these leukocytes are so numerous as to occupy the field completely. They are of the small mononuclear or lymphocyte group, although some polymorphonuclears as well as occasional large mononuclear blood-cells are present. At the end of the section behind the anterior stroma of connective tissue the lymphocytes have formed definite tubercles. They are round, and their periphery is bounded by a dense aggregation of small mononuclear leukocytes. The tubercles consist otherwise of large epithelioid cells, which occupy the center of each tubercle. Numerous giant cells are present. (Figs. 2 and 3.)

Although actual necrosis or caseation can hardly be said to have occurred, the cells most centrally placed have begun to show evidences of degeneration, being distinctly shrunken in size and contour. Their cytoplasm stains decidedly less distinctly than the cells more peripherally situated. Several sections were stained for tubercle bacilli, but none could be demonstrated.

An especially careful examination was made by high-power magnification for the detection of endothelial cells, which cover the anterior surface of the iris and line the cornea. That none of these cells could be found, and that the section is quite free from pigment cells, with which the iris is more or less infiltrated during chronic inflammation,

precludes the possibility that a superficial nodule has sloughed away from the iris and has formed a second focus of inflammation in the anterior chamber. A more reasonable conclusion would be that of a subacute or chronic inflammation of tuberculous origin, where the exudate particularly from the ciliary processes, consisted largely of lymphocytes, later to coalesce and form tubercles, which subsequently break down, rather than to treat of them as pus cells, as found in an acute hypopyon iritis. The action of light, penetrating a moderately clear cornea, may, in a measure, have arrested the progress of the disease in the anterior chamber, allowing a definite encapsulation of tubercules and lymphocytes more anteriorly to take place.

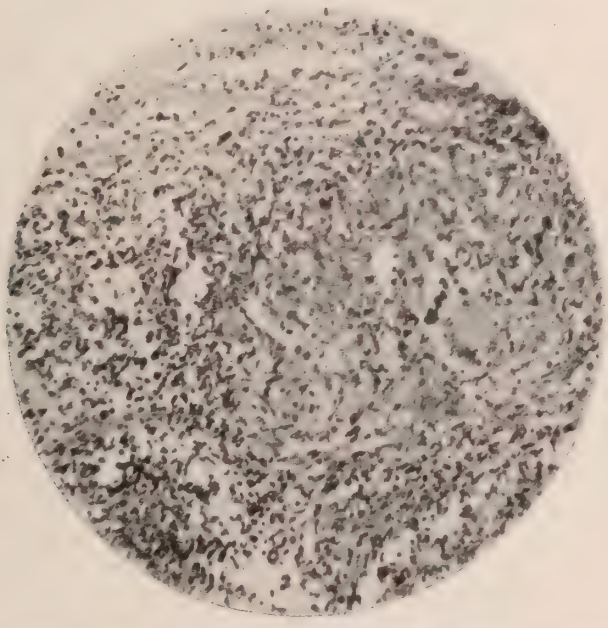

Fig 3. Case I. Section through a tubercle. Infiltration consists mostly of lymphocytes and a few large mononuclear cells and polymerphonuclears. Epithelioid cells and several giant cells also evident (high power).

Case 2.—Material supplied by Dr. Richard Kerry, Western General Hospital, Montreal.

I. R., a young English girl, aged eighteen years, complained of pain and redness of the left eye with intolerance of light. On examination the cornea at first suggested a condition of a superficial interstitial keratitis. There were areas of grayish streaks which tended to coalesce and to become more dense, with apparent roughening of the corneal epithelium. Under palliative treatment the eye became worse, infiltration of the cornea more intense, pericorneal injection more apparent, and the iris studded with a series of small grayish nodules. There were numerous posterior synechiae, the pupil dilating but slightly. There was an associated condition of cervical adenitis, presumably tuberculous; evening temperature, 99.2°.

The anterior chamber was opened on two occasions and iodoform powder introduced; iodoform emulsion was also administered hypodermically. The eye was subsequently enucleated by Dr. Kerry, as it was practically sightless, owing to corneal involvement and to the cataractous condition of the lens incumbent on the generalized posterior or ring synechia of the iris.

The globe was fixed and hardened in the usual way and subsequently embedded in celloidin. The section

shows very little evidence of acute or subacute inflammation at the corneoscleral margin, and the vessels are not excessive in number or altered histologically. There is no apparent infiltration about the walls of the blood-vessels, and the corneal epithelium shows no manifestation of edema or areas of exfoliation. Bowman's membrane is intact. Thruout the substantia propria there are innumerable areas of infiltration, which are most numerous near the limbus of the cornea. Each individual area is small, and does not appear to occupy more space than that of the single corneal cell, or at most of two cells. At no point do these assume a rounded or miliary appearance. The infiltration consists for the most part of small mononuclear leukocytes. There is no evidence of giant cells or of caseation in the cornea.

Descemet's membrane shows no presence of punctate bodies on its endothelial surface. There are areas where dense bands of adhesions have extended from the iris to Descemet's membrane, and where the latter has been ripped away by inflammatory bands extending from it to the anterior surface of the iris. These bands consist of inflammatory connective tissue cells, of various forms of leukocytes, in some instances with giant cell association, typical anterior synechiae.

The tear or separation of Descemet's membrane I interpret as mechanical, probably the result of opening the anterior chamber for the introduction of the iodoform. The iris is markedly infiltrated with large and small mononuclear leukocytes, as well as with some polymorphonuclears, to such a degree that details of the iris stroma and of its component vascular arrangement cannot be determined. Definite tubercles are scattered over the anterior surface of the iris, mostly over the pupillary margin. These consist of fibrinous material and of lymphocytes, with occasionally epithelioid cells, and others

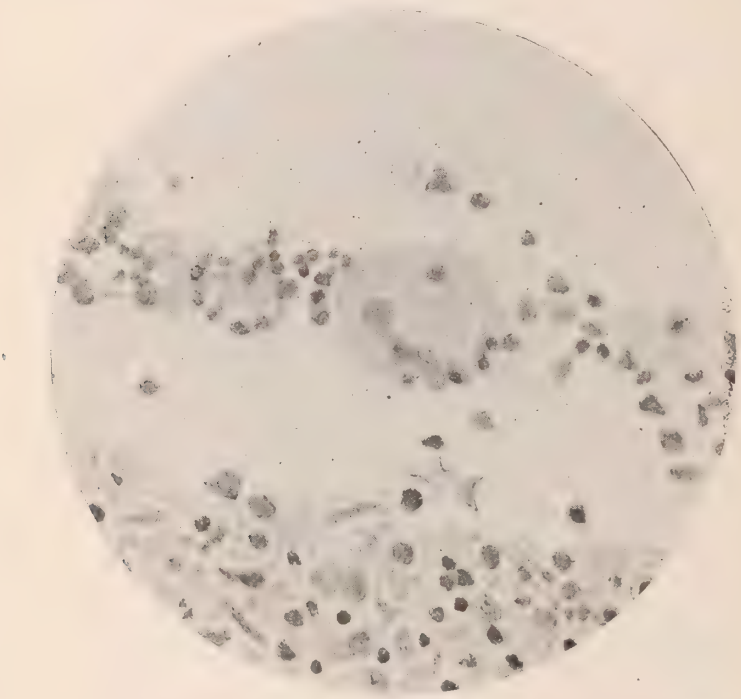

Fig 3. Case I. Practically same as Fig. 2, showing giant cells, leukocytes, fibrinous exudate, and endothelial cells lying free in the anterior chamber. (Oil immersion 1/12.)

in which an early stage of necrosis may be said to have begun. Giant cells are present. There are no evidences of tubercle about the filtration angle, altho one can be detected posteriorly midway between the pupil and the root of the iris (Fig. 4).

The pigment layer of the iris is distinctly disintegrated, and is thrown off into the posterior chamber. It has been collected at certain foci as definite masses, and when plastered down to the anterior lens capsule forms dense posterior synechiae, particularly about what was once regarded as the pupillary margin. At a greater distance from the pupillary margin these synechiae are less dense, and an iris bombe is clearly shown, with occlusion of the filtration angle.

Cataractous changes have occurred in the superficial lamellae of the lens cortex. A mild degree of infiltration is noticed about the ciliary processes, with numerous erythrocytes lying free in the vitreous chamber. The retina and choroid show no associated inflammatory changes. Tubercle bacilli could not be demonstrated in the tissues.

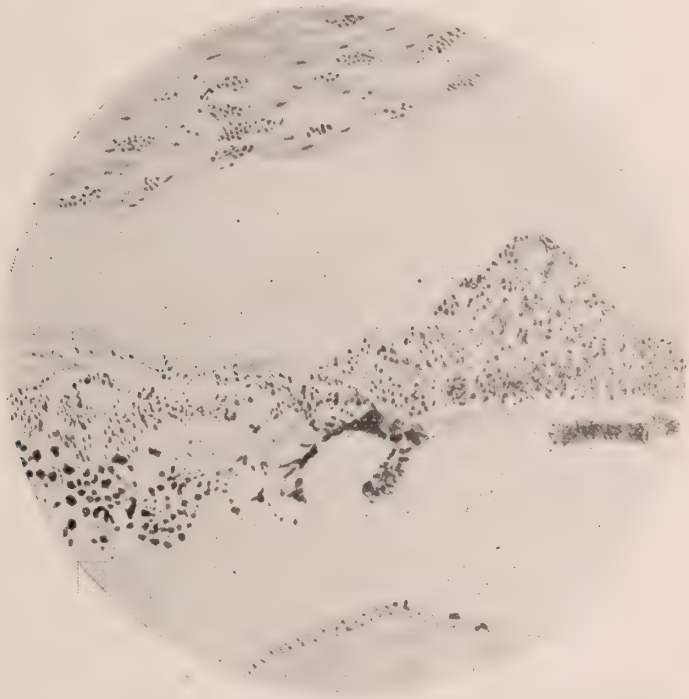

Fig. 4. Case 2. Marked infiltration of iris stroma with lymphocytes. Tubercle formation with giant cell near the pupillary margin of the iris. Pigment layer torn away posteriorly with evidence of its earlier attachment to anterior lens capsule.

Case 3.—Material supplied by Dr. W. G. M. Byers, Royal Victoria Hospital, Montreal

M. Y., female, single, aged twenty-seven years, consulted Dr. Byers for pain and inflammation in the left eye. She gave a history of the eye having been struck by a splinter of wood a month previously, but it gave her no trouble for three weeks' time. It then became red and she could not stand the light. The patient was a very poorly nourished woman, and altho a physical examination was made, no evidence of a general tuberculous lesion could be found. There was no history of tuberculosis in her family.

There was a small central opacity of the cornea, with considerable hyperemia of the iris. There were numerous

deposits on the inner surface of the cornea, apparently mostly central and to the temporal side. The pupil could be kept fairly well dilated. The cornea tended to assume a steamy or edematous appearance, and there was distinct tenderness over the ciliary body. There was no manifestation of tubercles of the iris, but subsequent examination was finally inhibited by a generalized interstitial keratitis.

Approximately one month after admission to the hospital the patient showed marked signs of improvement, although the cornea did not clear up. The evening temperature was 99°, morning 97.3°. She was finally discharged as she had an opportunity for convalescence in the country.

She was readmitted to the Royal Victoria Hospital two months later with the eye in an acutely inflamed and painful condition. The cornea was completely opaque and somewhat staphylomatous. Central ulceration had taken place, and a definite hernia of Descemet's membrane was evident, measuring less than 2 mm. across. She said that this had burst on more than one occasion. Details of the interior of the eye could not be obtained. The eye was naturally soft, and vision was reduced to perception of light only. There were no changes in her physical condition, and the temperature remained as at last entry. A smear of the conjunctival secretion showed a few Grampositive cells, later staphylococcus albus. The eye was enucleated by Dr. Byers. A von Pirquet reaction subsequent to enucleation was positive.

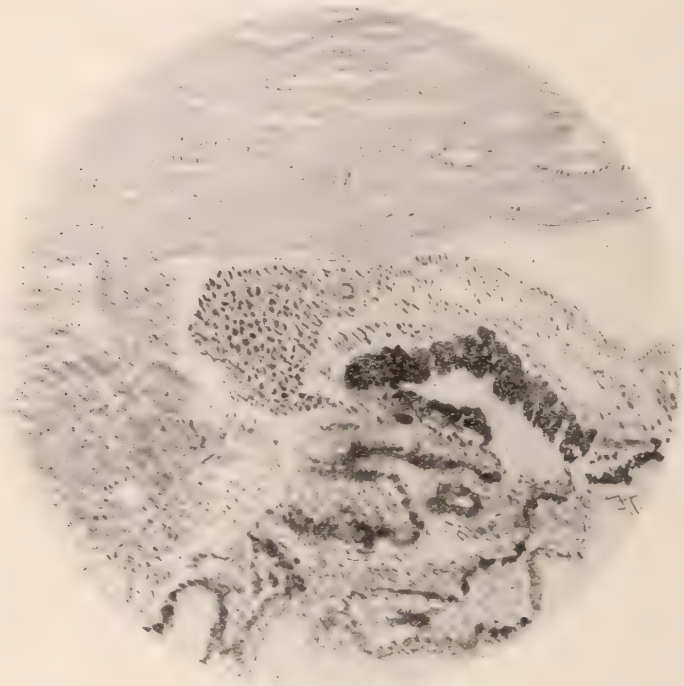

Fig. 5. Case 3. Marked infiltration of iris stroma with definite tubercle formation at root of iris, showing giant cell. Moderate degree of injection of ciliary body with infiltration of leukocytes about the ciliary processes.

On account of the necrotic condition of the cornea, this is the most complicated but by no means the most interesting of the sections. There is a marked condition of superficial as well as of deep injection of the pericorneal vessels. The deep vessels especially show a marked condition of dilatation, with clumps of leukocytes aggregated about the vessel walls.

The superficial layers of the corneal

epithelium are multiplied, and the deeper layers are edematous. The epithelium is distinctly irregular, dipping down into the diseased substantia propria as definite bud or nipple-like projections. Bowman's membrane is intact, but wavy and irregular in its course. Doubtless it is broken in other sections. Directly beneath this the cornea is distinctly vascular—naturally more so at the corneoscleral margin.

The substantia propria is markedly

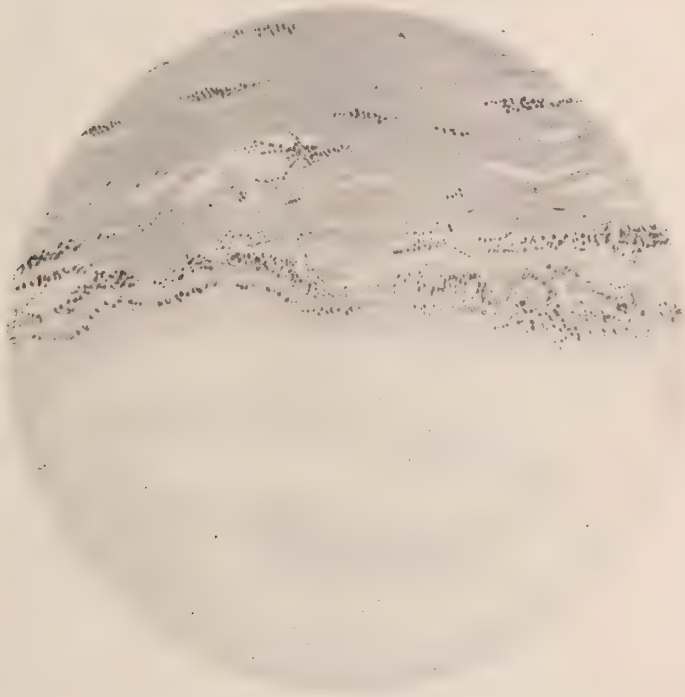

Fig. 6. Case 4. Taken near the filtration angle. Gradual necrosis of Descemet's membrane with groups of leukocytes adherent to its endothelial surface. Above it and between the deeper cells of the substantia propria is a marked infiltration of leukocytes with giant cell formation.

necrotic, the intercellular spaces being crowded with lymphocytes and with some pus cells. There are tiny blood-vessels in the cornea, the more superficial areas showing a condition of perivasculitis. A definite tuberculous nodule is well seen about the center of the substantia propria, fairly close to the filtration angle, and about midway between Bowman's and Descemet's membrane. It stains somewhat pale at the center, but there is no evidence of necrosis or of giant cell formation. The

center of the cornea is distinctly necrotic, being occupied entirely by granulation tissue. The granulation consists of a stroma of amorphous cells in which are included fibroblasts, lymphocytes, and the various elements of a chronically inflamed iris, pigment cells, and a mass of endothelial cells. Descemet's membrane is naturally broken and curled up at the point where the earlier ulcer formed. Where it is intact, numerous aggregations of lymphocytes line its endothelial surface. Numbers of leukocytes and fibrin lie free in the remains of the anterior chamber.

A definite tuberculous nodule with a central giant cell is apparent in the filtration angle, while another is even more evident in the ciliary body of the same side, close to the root of the iris (Fig. 5). The iris is injected and shows small tubercles in the process of formation in its stroma nearer the filtration angle. So much of the iris is

necrotic and amorphous, included in the ulcerated process of the cornea, one may reasonably suppose that the presenting portion may have formerly been more extensively diseased. There are, however, no giant cells in the portion of the iris included in the diseased cornea.

The ciliary body is moderately injected, the lining cells of the ciliary processes showing a manifest exhibition of leukocytes attached to their

oped suddenly seven years previously, when she was out of doors, at which time she experienced a sensation as of a grain of sand having blown into her eye. The eye recovered, but broke out with similar attacks on a number of occasions. It became perceptibly worse six months ago, when variations in temperature and bright lights would cause her a great deal of pain and photophobia. She was referred to the Royal Victoria Hospital.

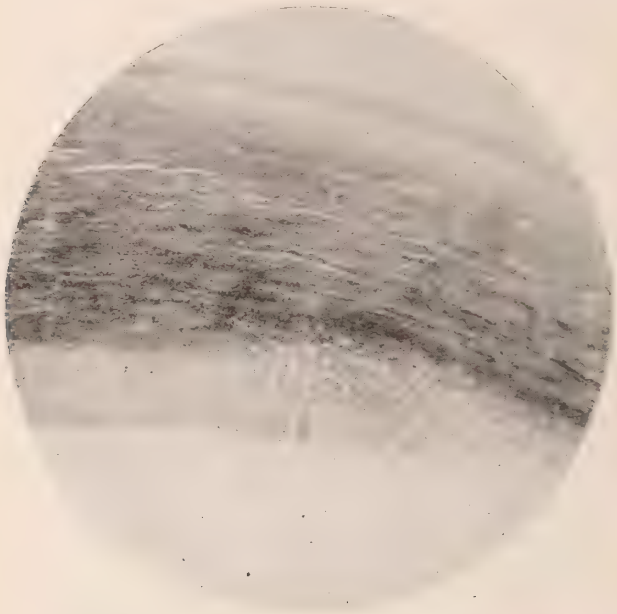

Fig. 7. Case. 4. Intense infiltration of substantia propria, especially the deeper layers. Lowest layer of cells actually necrotic, stain poorly, and innumerable giant cells are manifest (low power).

side, while other cells lie free in the neighboring vitreous, at least one forming a distinct clump—the nucleus of a later tubercle. Some of the retinal vessels are distinctly dilated, with perivascular exudate about their walls and with numerous leukocytes, chiefly lymphocytes and polymorphs, within the lumen of the dilated capillaries. A perivascular tubercle is well shown in at least one section. There is only a very moderate degree of infiltration in the stroma of the choroid.

Case 4.—M. M. C., female, single, aged forty-six years, consulted me complaining of pain and loss of vision in the left eye. The condition devel-

The patient was an unusually large but neurotic woman. Her previous health and family history were good. There was no evidence of focal tuberculosis elsewhere in the body after a very careful physical examination. The eye was moderately injected, with intense intolerance to light. The iris was discolored and would not dilate to any appreciable extent. There appeared to be no deposit peripherally on the endothelial surface of the cornea. The central portion of the cornea, or that considered as the area covering a moderately dilated pupil, was occupied by a dense, regular, deep seated grayish mass. The condition was dia-

gnosed as a tuberculoma of the cornea, and a diagnostic dose of 2 mg. of T. O. was given. The temperature rose from subnormal to 99.2°, and an acute reaction occurred in the eye. Therapeutic doses of tuberculin emulsion were then proceeded with, starting at 1/20,000 mg., but no improvement ensued. As the eye was practically sightless, and the pain was intensely acute, I enucleated the eye at the patient's request.

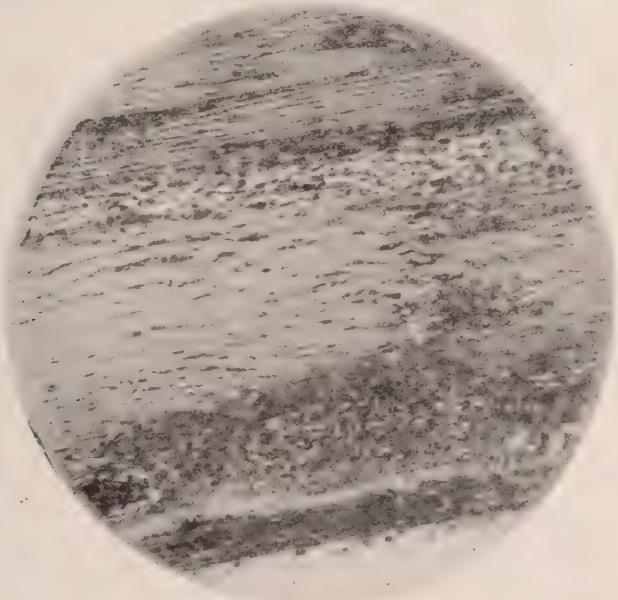

Fig. 8. Case 4. Shows character of infiltrtion of cornea. Deeper layers are actually necrotic, with area of infiltration assuming the form of a tubercle above. Necrosis of Descemet's membrane with marked proliferation of endothelial cells (high power).

There is marked superficial and deep injection about the limbus corneae, the deeper vessels showing a decided infiltration about the vessel walls. The more superficial veins are widely dilated and are filled with red cells. There is no edema of the corneal epithelium. Bowman's membrane is intact and, comparatively speaking, the superficial lamellae of the substantia propria are clear. As one proceeds more deeply there is an intense infiltration of the substantia propria (Fig. 7). This is so evident at the center of the section in the neighborhood of Descemet's membrane that actual necrosis is seen to have occurred (Fig. 8). The infiltration thruout the cornea consists practically entirely of lymphocytes. In the deep layers these have broken down and stain very faintly, constituting what has to be regarded amorphous cellular tissue. Scattered thruout this area are innumerable large giant cells.

Beneath this, at the center of the section, Descemet's membrane is also necrotic and cannot be recognized as such. It is clear, but lined with organized lymph or possibly by proliferated endothelial cells. There are numerous leukocytes or clumps of leukocytes attached to its endothelial surface at the more peripheral parts of the section.

The iris is markedly infiltrated and several small nodules can be seen on its endothelial or anterior surface. One nodule practically occupies the filtration angle at one point, while others may be recognized at the pupillary margin. There is no necrosis or evidence of giant cell formation in the iris, but the iris pigment is markedly disintegrated. The iris is intensely injected, and at one point has fallen forward, completely occluding the filtration angle. There is considerable inflammation of the ciliary body, and the

more anterior of the choroidal vessels show a decided injection about their walls.

COMMENT.

Parsons classifies tuberculous lesions of the iris as follows: (1) Miliary tubercule; (2) confluent or conglomerate tubercle; (3) tuberculous iritis. The last type may be indistinguishable clinically from other forms of chronic iritis, but microscopically sections reveal tubercle systems or the presence of bacilli.

The four cases just recorded may be considered to fall into the last mentioned class, not only on account of the clinical appearance of the various lesions, but also because of the peculiar chronic nature of each individual case when compared with the more acute lesions of classes 1 and 2. Parsons considers class 3 to be the rarest form of the disease in the iris, and refers to cases of Costa and Prunenda, Edmunds and Brailey, Knaggs, and Kalt. There is generally diffuse infiltration and thickening of the iris. Giant cells may be present, but tubercle systems not necessarily evident. Naturally necrosis with an exhibition of pus in the anterior chamber supports the diagnosis. The demonstration of tubercle bacilli is, naturally enough, conclusive evidence, but the diagnosis is not necessarily excluded on account of the inability of demonstrating the microorganisms. Animal inoculation may be of value. Diagnostic doses of tuberculin, in my own clinical experience, are not always necessarily positive.

Comparing the tuberculous with the syphilitic nodule, the opinion has been that the last mentioned occupies the root of the iris. Our more exact methods of diagnosis, as well as some of the more recent pathologic contributions, make us somewhat more guarded in indorsing such an assertion. For, if the statement be reversed, we note in case 2 of my series that the lesion appears anteriorly near the pupillary margin, but a second nodule may also be detected directed backward, and not far from the root of the iris. In case 3 a nodule is definitely at the root of the iris, and one also in the ciliary body, with a secondary or, more correctly speaking, associated tubercle in the substantia propria. In case 4 the infiltration is so intense that actual tubercle systems cannot be detected in the iris.

It is interesting to record in this regard that within the past three months I have had two patients with iritis developing very suddenly and from no apparent cause. In each case the nodule or nodules of the iris were quite evident about the filtration angle below, and an associated keratitis was present to an alarming acute degree. A Wassermann reaction of the spinal fluid was negative, but a positve reaction, both local and general, to tuberculin, in one case to 0.5 mg., in the other to 2 mg., added confirmation to a suspected diagnosis.

In the syphilitic nodule the iris tissue itself is of normal thickness, and the nodules fade away in the surrounding tissue. They may break thru the surface of the iris and communicate with the anterior chamber. They consist of mononuculear cells embedded in a fine reticulum. As in gummata, giant cells may be found, but rarely caseation. There are widely dilated capillaries within the nodules, while tubercles, on the other hand, are avascular.

No little interest is shown in the discrepancy of opinion as to whether the tuberculous focus in the iris is primary or secondary to a preëxisting tuberculous process. Leber, Fuchs, and de Wecker claim the disease invariably to be a secondary manifestation, while Parinaud, Lawford, Bach and others are as positive of the iris itself being the initial source of infection. In case 1, altho no primary source of infection could be actually pointed out, a very suggestive family history of tuberculosis would make one more than suspicious of a latent tuberculous lesion. Case 2 showed systemic manifestations of the disease in inflamed glands of the neck. Case 3, altho the most suggestive in appearance of all four, showed no actual le-

sion after careful clinical examination, but exhibited a positive tuberculin reaction after the eye had been removed. Case 4 was an actually robust, heavy woman, but gave a very marked local reaction to 2 mg. of T. O., with a corresponding general reaction.

It is further of interest to note that each of my cases was a female, ages ranging from eighteen to forty-six years. Seven out of eight human cases reported by Stock were also females, the manifestations of the disease appearing still later in life.

One cannot approach an intelligent appreciation of tuberculous iritis without recognizing the painstaking and scientific endeavor manifested in the work of Stock, on the one hand, and of Verhoeff, on the other. The latter has seen fit to disagree with the former in his work on the experimental production of intraocular tuberculosis in animals, Verhoeff preferring to inoculate dead bacilli or the toxins of bacilli directly into the anterior chamber or into some other part of the eye. Stock, on the other hand, preferred a mild dilution of the actual bacilli, which he introduced into the ear veins of rabbits. Altho Verhoeff's technic would at first glance suggest a more benign form of infection, as possibly more comparable with that exhibited in the actual process as it exists in man, yet Stock, by introducing the bacilli at a point away from the eye, allowed for a liberal dilution, also for such inhibition which the lymphocytes and leukocytes might supply. It is further questionable if, when the microorganism reached the eye, the reaction was more violent in the one series of cases than in the other. We must also not overlook the tremendous care and completness of Stock's undertaking. I can vouch for its thoroness, having been with him when part of it was in progress. Forty-eight animals were inoculated, and a careful clinical and pathologic examination, not only local, but also general, was systematically made of each individual case. That the effect of inoculation was not invariably unusually acute is proved by the fact that some rabbits lived up to two years after inoculation. Furthermore, in cases where tuberculous iritis was induced, healing in some instances took place in from two to five weeks.

Stock, from his experimental work on rabbits, has come to the following conclusions: The first symptom manifested is a general thickening of the iris tissue, without any unusual thickening of the blood vessels. Three or four days later small grayish masses appear in the iris tissue. As I have already given it as my clinical and pathologic experience, Stock supports my contention by affirming that there is no such thing as a site of predilection for the tubercle of the iris. It may appear at the pupillary margin, at the middle of the iris, or at the filtration angle. The nodules on healing leave a white spot. Some animals showed a generalized hyperemia of the iris, with the formation of new vessels and a general appearance of granulation tissue. Infiltration may be so intense that solitary nodules cannot be detected. Later there may appear changes in the surrounding tissues, as parenchymatous keratitis, with manifest pericorneal injection of the deep ocular vessels.

Pathologically the nodules, tho possibly having a site of predilection, are more numerous on the posterior than on the anterior surface of the iris. The nodules consist at first of mononuclear leukocytes without any epithelioid cells. Some nodules may reappear over the site of a previously healed tubercle. When left for a long time and allowed to increase in size, one notes in the center of the nodule large mononuclear cells with pale staining nuclei, epitheliod cells. One can only find giant cells in those cases where the process has been active for months, and tubercle bacilli could be demonstrated only in those cases where central caseation of the individual tubercle had occurred.

In the more malignant form, where a parenchymatous keratitis ensued, the iris was generally studded with tubercles. The center of such tubercles was generally necrotic. The sections, especially those from cases 3 and 4, show

a distinct disturbance of the endothelial cells of the cornea when a keratitis punctata is instituted at the back of the cornea. In the animals inoculated, as well as in the human cases recorded by Stock, Descemet's membrane always remained intact. Case 4 in my series is rather an exception to this rule or acceptance, where a fairly distinct atrophy or actual necrosis of this membrane may be seen to have taken place. Descemet's membrane behind is densely covered with lymph, and above by a distinct infiltration of lymphocytes and numerous giant cells in part of the cornea suggesting an early necrosis. On the other hand, case 3 demonstrates the absolute obstinacy and resistance of Descemet's membrane, presenting itself forward as a knuckle or hernia or descementocele after an actually complete ulceration of the substantia propria has taken place. The resistance of this form of a hyaloid membrane is quite comparable to that already pointed out by me in the case of the membrane of Bruch in cases of tubercle of the choroid. The whole cornea may be diffusely infiltrated, and new vessels may encroach upon the corneal tissue. There is a circumscribed nodule formation in the cornea itself, as well as about its margin.

An infiltration of the cornea is the rule rather than the exception in my experience. The ciliary body is not of necessity always acutely involved in the disease process. In gross involvement of the iris one may find large or small tubercles of the ciliary body. Stock was unable to find the same pathologic manifestations in animals as one would expect to find from clinical observations in the human.

This article would be far from complete were I not to attempt to acknowledge the important scientific work done by Verhoeff. His contribution on animal inoculation, as well as his reports on human tuberculous eyes pathologically examined, is more or less restricted in comparison with Stock's work. But his general approach of the subject and his astutely scientific interpretation of the possible transmission of the disease is more than on a par with the work of earlier writers. By introducing dead bacilli into the vitreous, or, for that matter, into the anterior chamber, he has shown that in several weeks, or even months of time, there may be produced nodules in the corneosclera closely simulating those of sclerokeratitis, as is manifested clinically in man. These have been manifested in a naturally modified form in all my cases, with definite lesions in the iris and ciliary body, and also in the retina, as I have been able to demonstrate in one case. In the case of a marked involvement of the cornea little reaction may be apparent in the ciliary body, a condition attributed to the fact that live bacilli, even tho of an attenuated virulence, will find the cornea and sclera more suitable for their proliferation owing to their avascular nature. The cornea is more involved in experimental work on animals directly inoculated, while the reverse is the case in man. This is as one would suppose or expect—in the one case the inoculation is almost direct thru the medium of the anterior chamber, in the latter instance it is indirect thru the venous capillaries of the uveal tract.

Verhoeff makes the statement that in his experimental cases the size and number of the lesions were greater at the filtration angle than elsewhere, showing that more bacilli lodged there. One might offer as an explanation the fact of the prevalence of tubercles of the iris occurring close to the filtration angle as borne out by Stock, as well as by myself. Sections from the cases which I am presenting do not necessarily always substantiate this fact, altho acknowledging the almost constant association of corneal involvement with tuberculous iritis. In the cases here recorded the iris itself is more involved than any other part of the eye. Furthermore, we notice in this series, as well as in the cases which I have had an opportunity of studying clinically, that the lesion in the cornea is more often opposite the pupillary area than about the filtration angle and ligamentum pectinatum. One may explain

such a condition by the fact of the toxins ultimately reaching that part of the cornea with the most stagnant supply of lymph, as one notices in any form of interstitial keratitis. Further, the aggregation of lymphocytes, with the attendant bacilli, are drawn directly from the posterior chamber thru the pupil to the anterior chamber. From albuminous changes in the aqueous and consequent alteration in its specific gravity these lymphocytes, instead of falling down into the filtration angle, fall more directly forward. Such a condition of so-called punctate keratitis, tho not perhaps an actual source of infection, has at least an influence in inhibiting nutrition from the aqueous, which we are led to believe supplies Descemet's membrane and the posterior layers of the cornea. These layers, with Descemet's membrane, are in consequence attacked from both sides. This interpretation has been shown to be more than a probability in cases 3 and 4.

There was evidence of an active or acute inflammatory condition in the choroid in one case only—case 4. Case 3 shows what might in time have developed into a retinal tubercle—a widely dilated vein filled with numbers of leukocytes, many, strangely enough, being of the polymorphonuclear type. There is distinct evidence of the migration of blood cells thru the vessel walls and of the formation of an early tho definite perivascular tubercle. Verhoeff, in his work, very properly supposes or suggests the probability of the infection, particularly as applied to the corneosclera, as coming from the lymphocytes escaping from lesions occurring in the choroid, retina, or ciliary processes. These clumps of cells, actually nascent tubercles, find their way thru the pupillary area, later to attack the cornea and corneosclera thru the ligamentum pectinatum. The infection is consequently direct and not one of metastasis.

In a former contribution which I had the honor of presenting before this society I attempted to show how, in cases of tubercle of the choroid, the condition extended thru the bloodstream. The migration of lymphocytes thru the vessel walls and the subsequent formation of a perivascular tubercle were demonstrated not only in the vessels about the base of the brain, but also in the pial capillaries extending into the vaginal space about the optic nerve. What is true in the acute form of the disease may, I claim, be equally true in the more chronic phase, tho from its mere chronicity not so easily demonstrable. One may thus account for tubercles found free in the vitreous, about the ciliary processes, in the choroid, and even in the more anterior portion of the retina in tuberculous iridokeratitis.

My observation in cases 3 and 4, while maintaining that the infection of the cornea is due to toxin and is endogenous, may still support Verhoeff's maxims. The aggregation of lymphocytes, or, what I have formerly termed them, nascent tubercles, after reaching the aqueous may find their way to the filtration angle and thru the ligamentum pectinatum, the toxins, or possibly the actual bacilli, to be taken up by the pericorneal lymph capillaries. A condition of parenchymatous keratitis may exhibit actual tuberculous elements other than ordinary manifestations of interstitial inflammation. I do not consider that the necrosis of Descemet's membrane in case 4 has resulted from direct apposition of tubercle upon its endothelial lining, any more than I have been able to demonstrate a diseased process in the membrane of Bruch in the acute form of the disease involving the choroid. My opinion is that a deep interstitial keratitis must first be present, with subsequent necrosis and doubtless with actual bacilli present rather than toxins. Case 3 supports this opinion, as well as the large series of cases prepared by Stock, who was unable to demonstrate a single case of initial necrosis of Descemet's membrane. Compared with his exhaustive series, both comparative and human, my own exception in case 4 would appear as a unique condition.

HEREDITARY CONGENITAL PTOSIS WITH REPORT OF 64 CASES CONFORMING TO THE MENDELIAN RULE OF DOMINANCE

H. H. Briggs, A. M., M. D.

ASHEVILLE, N. C.

This account of hereditary ptosis reporting a large family extending to six generations is slightly abridged from a candidate's thesis presented to the American Ophthalmological Society.

Near the summit of the Great Smokies, in western North Carolina and eastern Tennessee, on the head waters of Laurel and Nolichucky rivers, have lived for more than a century the strong, sturdy, and virile descendants of one Martin Maney, an emigrant from Dublin, Ireland, a veteran of the Revolutionary War, and one of the first pioneers to cross the Blue Ridge and brave the dangers of mountain wilderness and the Indians of those times—strong and sturdy, as evidenced by their ability to cope with the vicissitudes incident to pioneer life, and prolific, as shown by their large families —18 children in one, 10 to 14 in four, and 28 resulting from the union of one man (No. 17*) to three wives—15 to the first, 2 to the second, and 11 to the third.

Until recently these simple, poor, yet honest mountain people, isolated from railroads and thoroughfares, have lived in this sparsely settled country, where the high altitude, pure water, abundant sunshine, and the many other natural resources are conducive to happiness, longevity, and prolificity. Being content with their natural environment and with their innate love for the mountains, they have not cared to migrate into more populous centers, and on account of their segregation it has been possible to construct an accurate family tree, and to study the condition of hereditary congenital ptosis in many of the 64 cases recorded.

Case 1.—W. H. (No. 26), aged fifty-one years, farmer, in good health, has double ptosis, but no other evidence of physical or mental degeneration. Forehead greatly wrinkled, especially on right side. Eyebrows standing high. Width of nose, as between nosepiece of eye-glasses, 6 mm.; distance between inner canthi, 29½ mm.; distance between bridge of nose and inner canthus, 11¾ mm.; width of palpebral fissure, 24 mm.; diameter of cornea, 7½ mm.; distance from cornea to inner canthus, 8 mm.; pupillary distance, 55 mm. Upper lid shows no wrinkles, and covers the upper part of the pupil, necessitating constant action of the occipitofrontalis, and tilting of the head backward, in order to fix objects above the horizon. Patient able to superduct eyes, but this to only a limited degree. No other extraocular muscle impairment or imbalance; no pupillary reflex

*Only 18 of the 28 offspring appear on the family tree because of lack of data concerning remainder.

112 58 113

26 68 124

CASES OF CONGENITAL PTOSIS (BRIGGS)

disturbance nor impairment of the ciliary muscles save that due to presbyopia. When thumbs were pressed firmly against the eyebrows, so as to prevent the associated action of the occipitofrontalis, patient was unable to raise the lids showing total impairment of each levator. Refraction: V. R. E.=0.8, with sph.+0.50⊂cyl.+0.75 axis 15°=1; L. E.=0.8, with cyl.+0.75 axis 165°=1. Presbyopia, 1.50 D.

Patient states that he has never had any trouble with eyes except that due to the ptosis, which is borne out by the fact that he still uses an old cap and ball rifle for squirrel hunting. The patient's son (No. 68), grandson (No. 124), mother (No. 11), grandmother (No. 3), and great-grandmother (No. 1) were similarly affected.

Case 2.—G. H. (No. 68), aged twenty-five years, son of W. H., resembles in general stature his father, and has about the same amount of ptosis, but is the more able to correct the deformity by the associated action of the occipitofrontalis. Position of head slightly back. Patient able to superduct eyes, but this to only a limited degree. No other extraocular muscle impairment or imbalance; no pupillary reflex disturbance nor impairment of the ciliary muscles. Deep furrows in forehead, due to muscular attempt to raise lids. Width of nose opposite inner canthi, 11 mm.; distance between inner canthi, 35½ mm.; diameter of cornea, 7½ mm.; pupillary distance, 61 mm. Can lift upper lids slightly above pupil, but, as in case of the father, has no lifting power of upper lids when the action of the occipitofrontalis is checked by pressure over the eyebrows. Can turn eyes upward when lids are lifted, but this action is slightly impaired. Vision each eye, 1. No marks of degeneration.

Case 3.—C. H. (No. 124), son of G. H., four years old, slightly undeveloped. Has marked ptosis. Upper lids hang below upper margin of pupil, necessitating extreme backward position of head in attempting to fix objects in horizontal field. Small wrinkles in forehead, indicating auxiliary action of the occipitofrontalis. No other extraocular muscle impairment or imbalance; no pupillary reflex disturbance nor impairment of the ciliary muscles. On lifting eyelids with fingers, patient is unable to lift eyes above the horizontal meridian, indicating impairment of the superior recti, but since his father, aunt, and grandfather possess this power of superduction, it is probable that this function will be acquired in later years. Base of nose very broad, measuring 20 mm., compared to 6 mm. of the grandfather and 11 mm. of the father. Distance between inner canthus and side of the nose, 9 mm.; width of palpebral fissure, 20 mm.; height of palpebral fissure, 6 mm.; pupillary distance, 52 mm. Unable to determine vision, but no evidence of defect.

Case 4.—Mrs. McK. (No. 70), aged twenty-three years, daughter of W. H. (No. 26), has the least amount of ptosis observed in any of the genealogy. Has very narrow nose, like her father; eyebrows highly raised; the skin over the forehead corrugated on account of the contraction of the occipitofrontalis in an effort to assist the levator. Ptosis more marked in the left. On exerting pressure over the supraorbital region, preventing action of the frontal portion of the occipitofrontalis, patient still able to slightly raise the upper lid, showing that the action of the levator in this case is only partially paralyzed. The lacus lacrymalis is very broad vertically, extending downward, inward, and forward. Distance from inner canthus to the side of nose, 8½ mm.; distance between inner canthi, 36 mm.; width of palpebral fissure, 23 mm.; vertical width of palpebral fissure, 6½ mm.; pupils, in moderate light, 3½ mm.; crest width of nose, 14 mm.; pupillary distance, 64 mm. On looking straight forward, upper lid covers upper part of pupil. On attempting further upward motion the occipitofrontalis is called more and more into action. Vision above 20 degrees impossible without bending head backward.

Case 5.—Male infant (No. 81), six weeks old, in splendid health, has very marked ptosis. There is no evidence

of action of the occipitofrontalis as an auxiliary aid to the levator, and, as the levator has no action, the lids scarcely separate, there being perhaps about 1 mm. opening. Palpebral fissure very narrow to the extent that blepharophimosis exists. Lifting upper lids causes immediate photophobia, but reveals eyes normal in appearance. Unable to test extrinsic muscles, but no evidence of their impairment.

Case 6.—(No. 111.) Girl, aged fifteen years, in good health, moderate amount of ptosis; total impairment of function of levators. Has congenital contraction of the subcutaneous tissues over the malar, or attached to same, drawing the lids to the outer canthus, especially the lower, far away from the eye. This contraction of the lower lid stretches the lower canaliculus, misplacing the lower punctum 7 mm. from the inner canthus, and gives a general appearance to the eyes of convergent strabismus, but this is only apparent, as there is no muscular imbalance. There is a chronic granular condition of the lids, due to their exposure, and the cornea in the lower outer quadrant, for the same reason, is roughened, rendering the vision 0.5 in the right eye, that in the left being normal.

The six cases above reported represent the fourth, fifth and sixth generations. Cases Nos. 81 and 124, infants in the sixth generation, have seemingly an equal if not a greater amount of ptosis than had case No. 26 or case No. 58 in the fourth generation, or of any shown in any of the photographs, which would indicate that the degree of ptosis remains constant, and is at least not becoming diluted.

Summary.—The cases of hereditary ptosis herein recorded are members of a genealogy extending thru six generations over a period of one and one-quarter centuries. Inheritance in every case is direct, no generation in the lineage of the affected being skipped except in the one instance, Case No. 125, in the sixth generation, whose mother, No. 90, a member of the genealogy, is said to be normal, and to have married one who was also normal.*

Twenty-three families are represented, in 17 of which the father, and in 6 the mother, transmitted the malformation. In no case did affected parents fail to transmit ptosis to one or more of their offspring.

There was only one case of intermarriage,† and that between affected female No. 43, in generation four, to a normal male, second cousin, No. 109, in generation five. Of the two male offspring, one was affected and the other normal.

Of the 128 members of the genealogy composing the 23 affected families, 64 were affected with ptosis and 64 were normal; 74 were males, 53 females, and one of unknown sex. An equal num-

*Information gained from relatives.
†Mountain people seldom intermarry.

ber (64 of each), were affected and normal. Of the affected, 33 were males, 30 were females, and 1 of unknown sex, while of the normal, 41 were males and 23 females.

Of the twenty* affected parents, 16 were males and 4 females. Of the 121 offspring (71 males and 50 females), 61 were affected and 60 normal. The 16 fathers had 100 children (62 males and 38 females), to 47 of whom they transmitted ptosis, there being 53 normal. The four mothers bore 21 children (9 males and 12 females), of whom 14 had ptosis and 7 were normal. Of the offspring, 61 had ptosis and 60 were normal, the fathers' share was 47 ptosis to 53 normal, while the mothers' was 14 ptosis to 7 normal. Of the 71 male offspring, 62 were from affected fathers and 9 from affected mothers, while of the 50 female offspring 38 were from affected fathers and 12 from affected mothers.

Literature.—Ptosis unaccompanied by motility defects of the eye is seldom seen. Epicanthus and impairment of function of the superior rectus most frequently exist, yet paralysis of each and all of the extrinsic muscles has been noted. In no case found in the literature has paralysis of the intrinsic muscles of the eye been a complication of ptosis, except in complete ophthalmoplegia. Disturbance of the pupil and accommodation are, therefore, practically never seen associated with ptosis.

Hirschberg[17] found a case of ptosis accompanying total ophthalmoplegia in a child whose mother and grandmother were similarly affected. Schiller[35] reports father and two sons having ptosis with paralysis of all the outer eye muscles. Horner[19] reports inherited ptosis through three generations of one family, and in nine brothers of another family, associated with impairment of the superior rectus. Rampoldi[33] reports ptosis in father, son, and daughter, with immobility of the extrinsic muscles and slight astigmatism. Daguillon[9] reports congenital hereditary ptosis with divergent strabismus, congenital hereditary myopia, and amblyopia. Lawford[25] reports ptosis in father and three sons among seven children, immobility of the eyes in the vertical meridian, with only slight amount of mobility to the side. Horner[19] reports cases of ptosis in several generations of the same family. Heuck[16] reports ptosis in mother, two sons, and one daughter, in which the eyes were directed downward and easily converged. There was complete loss of function in the superior and inferior recti, while the other extrinsic muscles functioned. There was also deficient vision. Hirschberg[17] reports ptosis in a mother, daughter, grandson, and great-grandson, with impairment of superduction, abduction, and adduction. In the grandson, epicanthus, superduction impossible, and divergence alternating with convulsive convergence. Vignes[43] gives cases of ptosis and epicanthus in grandfather, five sons, and one daughter of 11 children. He also reports ptosis in a father, two sons, and one daughter of 5 children. Vossius[44] gives history of two brothers with impossible movement of the eyes in the vertical meridian and dimness of vision. Ginestous[12] reports child of twenty-five months showing incomplete ptosis, epicanthus, and paralysis of the superior rectus. Ahlström[1] reports case of ptosis and ophthalmoplegia externa in a fifteen-year-old boy, and history of several relatives similarly affected. Guende[15] reports three brothers in family of nine children with ptosis complicating ophthalmoplegia externa. Dujardin[11] reports maternal grandfather, mother, and four daughters having ptosis with immobility of the eyes upward and downward and limitation of lateral movements. Schiler[35] reports ptosis in grandfather, father and son, with immobility of the outer muscles, high hypermetropia, and a dot-like darkening of the lens. Gour-

*Leaving off the progenitor, father of No. 1, parents who intermarried, and No. 90 (mother of S), from total number of parents.

fein[14] reports ptosis in grandfather, father, and four sons, the female members of the second and third generations remaining healthy. Movements of the eyes always accompanied by rotary nystagmus. They also showed amblyopia, changes in the optic nerve and the retina, flattening in the region of the eyebrow. Ayres[4] reports grandfather and uncle with immobility of all eye muscles. Paul Bloch[7] reports two brothers having paralysis of the abducens and ptosis.

Steinheim[39] reports ptosis and epicanthus in five generations. The great grandfather had ptosis. Of his five children, two males and one female were affected. One male and one female married and moved to America, no more being known of their descendants. The other male married, had two daughters, one normal and one affected; the latter becoming the mother of five children, of whom two males and one female were affected. Of the girl's children two were normal and one affected. Of the two males, one became the father of two normal and two abnormal children, while the other was father of three abnormal and three normal offspring.

Hüttemann,[21] in 1911, reported 11 cases of congenital hereditary ptosis and epicanthus in three generations of the same family. He notes that in all these there was a peculiar lid movement associated with lateral movement of the eyes. In a glance to left the right eye, and on looking to the right the left eye, was almost closed.

Dujardin[11] reports five cases of congenital ptosis in grandfather, mother, and three daughters, the fourth daughter being normal. One of the affected daughters had partial ophthalmoplegia.

H. P. Stuckey[40] reports father, son, and three grandsons living in northern Georgia having ptosis, one daughter being normal. These are Nos. 25, 64, 65, 66, and 67 of the genealogy of the author's cases. He considered it a probable example of Mendelian recessive. The inheritance is, however, dominant in character, as is amply illustrated in the extensive family tree.

F. R. Spencer[37] reports a case in a man of twenty-seven who gives history of ptosis since fifteen or sixteen years of age. He thinks it has gradually increased since that time, but has been much worse for the past three years. His mother, maternal grandmother, two maternal aunts, and one brother were similarly affected. His younger brother's lids began to droop at the age of twenty-two years. His mother had great difficulty in raising her lids. His abduction, adduction, superduction, and subduction were very limited, and he was unable to raise either eyelid without the assistance of the frontalis muscle.

Pathology. — Operations, autopsies, and microscopic examinations have revealed the following condition as causes of ptosis:

(*a*) Defective development of levator and other muscles of the eye. Heuck[16] found a partly developed levator measuring only 2 mm. in breadth. Bach,[5] in a case of bilateral congenital ptosis and limitation of the eye movements upward, found defective development of levator and moderate atrophy of superior rectus; the nuclear region of the oculomotor was normal.

(*b*) Adhesion of Muscles.—Albers and Wrisberg[2] found in a case of ptosis adhesion of the rectus superior with the levator; the external rectus was adherent to the inferior rectus, and the internal rectus to the superior oblique.

(*c*) Abnormal insertion of muscles was found by Rossi,[34] Heuck,[16] Dieffenbach,[10] Pflüger.[32] In some of the cases the superior rectus was found inserted back of the equator.

(*d*) Connective-tissue bands instead of muscles were found by Ahlström[1] in cases of congenital ptosis. When he laid bare the tarsal border in the left eye, no trace of the levator tendon was seen, and in the right eye only a few scattered tendon fibers were found.

(*e*) Absence of Muscle.—Lawford,[25] in a case of ptosis with divergence, found the rectus internus absent. Ahlström[1] found no trace of the levator, and Heuck[16] reports finding the same condition. Horles[18] reports a case of ptosis in which both obliques were lacking, the recti being normal. Seiler[36] found a case

of ptosis in which the inferior oblique and superior rectus of the right eye and the inferior oblique of the left eye were lacking. In another case the superior and inferior obliques of the right and the superior and inferior obliques and superior rectus of left were not found.

Steinheim,[38] in a case of congenital ptosis with defective motion of the eye, failed to find the superior rectus.

Etiology.—The etiology of ptosis leads back to the question of the cause of variation, and has been defined as the event which brings about the addition or omission of a factor. It is due either to absence of the factor for the normal development of the levator, or to the presence of an inhibitor to normal development.

Intermarriage, certainly in the last six generations, has not been a factor in the heredity of ptosis in this genealogy. Of the 128 offspring whose histories have been studied, there has been but one intermarriage, that between the affected female (No. 43) in the fourth generation and her second cousin, normal (No. 109) in the fifth generation. From this union resulted one normal male, three years old, and one male six weeks old.

There is one other instance of intermarriage between female (No. 36) and son of No. 21, who was grandson of No. 4, abnormal, two generations removed, and consequently not included in the numbered offspring. This union resulted in all normal.

It is very difficult to determine the exact anatomic cause of the anomaly. Because of their anatomic situation, it is impossible to test the muscles of the eye electrically. Koster[23] reasoned that, if the enlargement of the palpebral fissure is considered, the levator muscle of the lid exists but is paralyzed or atrophied. Since the tarsal muscle of Müller is inserted in the lower part of the tendon of the levator, if the latter is lacking, the tarsal muscle has no point of insertion and cannot raise the lid under the influence of cocain. Cocain, therefore, reveals the absence or presence of the levator. The use of this method in the author's cases examined, resulted, so far as revealing a cause, negatively.

The author thus far has not had an opportunity of operating on any case of ptosis in this genealogy, or to note the exact pathologic cause of ptosis at necropsy. He hopes, however, to operate on case No. 111, and to soon make a supplemental report of the findings.

Diagnosis.—Ptosis is either congenital or acquired, and these again may be subdivided according to the causes which produce it. It may also be unilateral or bilateral. Although some hereditary eye diseases, such as certain forms of cataract (Nettleship[31]) which occur in middle life, are not congenital, all cases of hereditary ptosis are congenital. In other words, hereditary ptosis is prenatal, manifesting itself at birth and continuously. In hereditary congenital ptosis, which is usually bilateral, there may be absence or deficiency of the levator often associated with absence or deficiency of one or more of the extrinsic muscles of the eye, most frequently the superior rectus, and most frequently of all it is associated with congenital epicanthus. There may be absence or deficiency of that portion of the third nerve supplying the levator. It is sometimes associated with sympathetic movements of the lower jaw, increasing in degree when the eye is abducted, and disappearing when it is adducted, the lid in these cases constantly retracting involuntarily when the jaw is moved to the opposite side of the ptosis (Bradburn[8]).

On the contrary, in an acquired ptosis there is usually to be found an affection of the lids, such as hypertrophy, edema, new-growth, blepharochalasis, and ptosis adiposa. It may result from trauma to the levator, or atrophy, as occurs in women of middle life, or as an early symptom of chronic progressive opthalmoplegia and myasthenia gravis. It may result from a central or cerebral degeneration. When due to a cortical lesion, it would probably be unilateral, and the only eye lesion, the other branches of the oculomotor nerve being unaffected. A nuclear lesion of the pons might produce such a lesion (Bradburn[8]). Ptosis, as a symptom, may result from constitutional diseases, such as myasthenia gravis, locomotor ataxia, toxic processes, chronic progressive ophthalmoplegia, hysteria. Acquired ptosis may also occur from

nuclear, fascicular, or basal lesions, from sphenoidal abscess and orbital lesions, and from affections of the sympathetic nerve.

The author's cases of ptosis are unique in that in no case is the ptosis complicated by any other motility defect except in the infant (No. 124), whose superior rectus did not function, and this probably not because of any defect in the muscle itself or impairment of its nerve supply *per se,* but on account of the drooping of the lid the superior rectus had never been called upon to turn the eye upward. When the child was asked to look at an object held above his horizon, he invariably tilted the head backward until the visual plane met the object, and this he did even when the lids were lifted by the observer. Observation of the eyes during sleep or under general anesthesia might have determined whether or not superduction was possible, but such opportunity was not offered.

In case No. 59 it was demonstrated that the levator had a certain amount of function, but in no other case examined could function of the levator be demonstrated.

Mendel's Theory.—The Mendelian phenomena are well illustrated in peas, mice, rabbits, poultry, and snails. Certain defects: hornless cattle—polled angus, earless sheep of China, tailless cats of Japan, short-tailed dogs and pigs are also examples of Mendelian phenomena. That we do not find more examples of Mendelian inheritance in man is due to the fact that the inbreeding necessary to bring out Mendelian segregation is not sufficiently close in man.

The eye and its appendages are subject to more hereditary diseases and malformations than in any other organ, due partly to the great number of histologic and anatomic structures concerned in its makeup, and partly to its many complicated and coördinated physiologic functions, which are so easily disturbed. Of ophthalmic disease most frequently transmitted may be mentioned: ptosis, epicanthus (Manz[27]), distichiasis, nodular and reticular opacities, corneal staphyloma, aniridia, coloboma of the iris, corectopia, cataract (Nettleship[31]), ectopia lentis, glaucoma, retinitis pigmentosa (Leber[26]), and other retinal degenerations, night blindness, nystagmus, color blindness, albinism, motility defects and errors of refraction. Of these, those showing the most marked evidence of transmission are cataract, night blindness, and motility defects, including ptosis. Most of the transmitted defects of the eye follow Mendelian rules, and, with the exception of those which are sex-linked, as color blindness and stationary night blindness, are *dominant* to the normal.

In order to discuss more intelligently the inheritance in the cases of ptosis herein reported, let us recall briefly the salient points of the Mendelian theory.

Gregor Mendel,[28] in 1865, experimenting with the edible pea (pisum sativum), took a pair of characters, tallness and shortness, and crossing the tall variety of six feet with the dwarf of one foot, it was found that the first cross-bred variety, F 1, were all tall. From the fact that the character tallness appeared in all the cross-bred, to the exclusion of the opposite character, dwarfness, Mendel called it a *dominant* character, and dwarfness, a *recessive* character. The tall, cross-bred by self-fertilization, bore seeds which produced a mixed generation, F 2, many being tall and some being short, like the tall and short grandparents, respectively, and in the ratio of about 75 per cent. tall and 25 per cent. short. The F 2 plants were again allowed to self-fertilize themselves, and it was found that the dwarfs (recessives) produced dwarfs entirely, and that further propagation of these produced pure recessives. But the tall, F 2, dominants, produced (instead of all dominants as the dwarfs produce recessives) two kinds: (*a*) plants of mixed F 3, consisting of tall and dwarfs in the proportion of three to one respectively, and (*b*) plants which gave tall only, and are those pure to tallness; the ratio of the impure (*a*) plants to the pure (*b*) being two to one. The F 2 generation dominants was composed, therefore, of three kinds of plants:

3 { *Dominants,* pure, 25 per cent.
3 { *Dominants,* impure, 50 per cent.
1 { *Recessives,* pure, 25 per cent.

Mendel found similar inheritance as above noted when all the other distinct characters in peas were used, the dominant character being shown in italics as follows: *Tallness*—shortness. *Flowers along axis* of plant or on top of plant. *Green color of unripe body*—yellow color of pods. *Shape of body inflated*—constricted between seeds. *Red seeds*—gray or brown. *Yellow cotyledons*—green. *Round seeds*—wrinkled.

Segregation and allelomorphism. Tallness (D) and dwarfness (R) (Bateson[6]) entered in the fertilized ovum in the original cross, but since the next generation showed some tall and others dwarfs, there must have been a separation (segregation) of the two characters in the process of the germ formation in the fertilized ovum (zygole) of the two characters, the segregated characters being called allelomorphic. This was shown in crossing F 1 with pure dominants and pure recessives. D R multiplied by D D gave all dominants in appearance, although composed of D R and D D plants equal in number on the average. On the other hand, D R multiplied by R R gives an equal number of dominants and recessives; the dominants being D R and the recessives being all pure recessives. This ratio of one to one, which results from D R multiplied by R R, will be referred to later in relation to the inheritance of ptosis.

If the character ptosis is dominant, the normal being recessive, there should be, in the aggregate, approximately the same number of affected and normal offspring. There were found 64 cases of ptosis and 64 normals, which conforms with mathematical precision to the rule of dominance.

In this connection it is interesting to compare the ratio of affected and normal in cases of hereditary cataracts taken arbitrarily from Nettleship's reports, as follows:

Recorder	Affected	Unaffected
Berry	20	20
Fukala	19	22
Nettleship	29	25+
Zirm	14	15
Nettleship and Ogilvie	17	25
Total	99	107

Dominants.—The following points, quoted from Bateson,[6] differentiate between dominants and recessives. "Dominant characters will, in general, be recognized as such from the fact that they are transmitted through affected persons only. The dominants will, as a rule, have one parent affected with the peculiarity and one part free from it. It is then to be expected that the children of such dominants, resulting from their marriages with unaffected persons, will show equal numbers of affected and normal. Recessive characters will be recognized by the fact that they may appear in the children of parents not exhibiting such characters, and especially among children born of consanguineous marriages. Complete proof of the recessive nature of a characteristic will be obtained only by evidence that all the children of affected parents exhibit the characteristic."

From this we reason that the author's cases conform to the Mendelian law of dominance, because—

(*a*) The transmission is thru affected persons only; there being no case where the inheritance was through an unaffected parent, except in case No. 125, a child whose mother is said to be the only normal of seven children. As this information was obtained from relatives, it is entirely possible that a slight degree of ptosis in her case might be considered normal compared to the marked degree which the other six are reported to have.

(*b*) In every case the dominants (ptosis) have one parent affected and the other parent normal. There is only one case of consanguineous marriage among the cases reported; that being between an unaffected male in the fifth generation (No. 109), wedded to an affected female (No. 43) in the fourth generation; the relationship being that of second cousins, and resulting in one affected and one normal offspring, according to the rule of dominance.

(*c*) The ratio of 64 dominants (ptosis) to 64 recessives (normals) conforms to the third qualification of dominants which requires an expectancy of an approximately equal number of normal and affected children descending from dominants (ptosis).

(*d*) That it is not a recessive charac-

ter is shown by the fact that in no case was an affected child born from normal parents, one or the other parent invariably showing the character, except in the one case, No. 125, and as this information was gained from relatives, there is a possibility of it not being correct.

(*e*) Thus far there has been no opportunity to determine what would be the result in the offspring where both parents are affected.

Sex-linkage.—Certain ocular diseases of the dominant type follow a sex-limited descent, notably color blindness and night blindness. The distinguished differences in the sex-limited, from the pure dominant types of inheritance, are that in the former—

(*a*) The males are affected more frequently than the females.

(*b*) It may be transmitted by affected males, but never by the unaffected males.

(*c*) It is transmitted by unaffected females.

(*d*) Apparently normal women, daughters and sisters of affected males, transmit the condition to their sons.

In no case in the genealogy save two was an affected child born to a normal parent. These are case No. 1, the first member of the genealogy, an affected female resulting from the union of Martin Maney, an Irish descendant, wedded to Kissia Van, a quarter Indian, both of whom had normal eyes. These cases were not examined, as they lived in the latter part of the eighteenth century, but this information comes from so many reliable sources, and especially from the oldest inhabitants in the neighborhood, that its correctness can scarcely be doubted.

Quoting from a letter from Dr. I. L. English, who was reared in that country, and has been the only physician practising there: "Martin Maney, who came when a boy from Dublin, Ireland, married an Indian. John Metcalf (No. 24) thinks that Martin Maney was little-eyed, but I learn from other old people that he was not; that when his first child (female No. 1) was born, little-eyed, the friends made alarm about the child's deformity, and its father (Martin Maney) told them to not worry, that most all his people in Ireland were little-eyed." This is the first instance of an affected child born of normal parents.

The second case is that of No. 125, sex unknown, said to be affected, born of normal female (No. 90). This family lives in middle Tennessee, and I was unable to verify the statement. It is quite possible that in a family where five of the six children have ptosis, the sixth child might, by contrast, appear normal, when in reality it might have a moderate degree of ptosis. Granting that the information is correct, it would probably mean an instance of recessiveness such as perhaps happened in the case of F 1, the first member of the genealogy. Except in these two cases the inheritance is purely dominant in character.

THE DEVELOPMENT OF A TONOMETER.

William McLean, M. D.

NEW YORK, N. Y.

This account of work done to place tonometry on a more accurate scientific basis includes some notice of inaccuracies that have heretofore been admitted, and observations regarding the normal intraocular pressure.

The features I set out to improve or eliminate in the Schiötz and Gradle tonometers (and that was all I intended doing), were:

1. To avoid the changing of weights.
2. The elimination of the chart to determine the pressure in mm. Hg.
3. Placing the reading scale nearer to the cornea, so the same person could more easily apply the tonometer and make his reading.
4. Prevention of capillary attraction between plunger and barrel, of fluid from the conjunctival sac.

I made three different tonometers, then tried modifications of them, and finally decided on one which I handed to the Meyrowitz Co. to use as a sample in constructing them on a quantity basis.

I was about three years working on one and another models, trying to overcome the several mechanical difficulties encountered before I was ready for the scale and the determination of the pressure according to the manometer.

It was not until I was ready to work out the scale that I ran against my first real snag. I constructed a testing apparatus using a Riva-Roche manometer, and of course in that type I had to use air as my medium of connection

in the tubing connecting the testing apparatus (manometer), and the testing eye.

In order to satisfy myself that everything was O. K. I tried to test it out with a Schiötz tonometer and to my surprise I could not get the tonometer and manometer to agree. I examined my apparatus, but could find nothing wrong, so put on another eye and my readings with that eye were no better than the first. I borrowed a Schiötz; but that gave me no light as to what was wrong. I used a third, with no better results. A Gradle was tried and that would not agree with the manometer. All these tonometers gave lower readings than the pressure as indicated by the manometer, and I could not determine what was wrong.

Thinking that Dr. Gradle must have worked out a testing apparatus I wrote him and received a reply that he had not been able to get a satisfactory testing apparatus; so used as his standard a Schiötz that he know to be correct.

As a could get no help from that direction I went to a professor of physics at Columbia University. He looked over my work and assured me that it was all according to the laws of physics, and if the tonometer and manometer did not agree, it was the tonometer that was at fault.

I then invited Drs. Holzapfel, Hallet, Helfrich, Marple and Schoenberg, at different times, and it was as much of a surprise to them as it had been to me to find that the Schiötz and manometer did not agree. All of these men used the instrument themselves.

Dr. Helfrich hit on the novel idea, which was to try his sense of touch to determine the pressure. I adjusted the pressure to 20 mm. (the mean normal according to Schiötz), and he pronounced it a soft eye. Then without his knowledge of the pressure I increased it until he judged it to be normal according to finger palpation, and at that time the manometer registered 40 mm. (These were enucleated eyes and his fingers were applied directly to the eyeball instead of thru the eyelids as is the custom for finger measurement of intraocular pressure.)

I repeated this stunt with Dr. Marple. He pronounced 20 mm. as a very soft eye and stopped me at 42 mm. as normal. I tried the same thing with Dr. Schoenberg with a similar result, but I failed to make a record of just what he considered normal.

The water manometer was tried and that gave me approximately the same result; and as that is more convenient to manipulate I use it exclusively now.

Dr. Marple had seen Dr. Schiötz testing apparatus, and pronounced it quite similar to mine, altho he complimented me on one or two points which he considered superior to Dr. Schiötz'. He said my method of connecting the tubing to the eyeball was an improvement as I did not have any leakage there, while Dr. Schiötz, he said, was bothered considerably with leakage. Also I had constructed an apparatus which I called a pulsator, which simulated the blood stream pulsations in the eyeball of the living. This apparatus did not alter my readings but rendered them a little more delicate.

None of these men were able to give me any clue as to why the Schiötz and manometer did not agree. I then tried some experimentation on the living animal, a summary of which is given in my article referred to, and which generally showed much higher readings with the manometer than were indicated by the Schiötz tonometer.

I was particularly fortunate just about this time in being allowed to experiment on a person whose eye was to be enucleated on account of glaucoma. I did not think it advisable to alter the intraocular pressure by manipulating the manometer while the interior of the eye was connected to the manometer; but we were able to make some changes in intraocular pressure by manipulating the anesthesia.

After this eye was enucleated I was able to make comparisons and confirm the experiment. The results of this experiment were readings indicating 50 mm. of intraocular pressure by the Schiötz tonometer and 65 mm. Hg. by the manometer.

At this stage of the proceedings Dr. Marple, who had become greatly in-

terested, asked the privilege of sending to Dr. Schiötz one of my tonometers together with a diagram of my testing apparatus and the results of the tests he had seen, and the test on the human eye, as he claimed the distinction of bringing the first Schiötz tonometer into this country.

He wanted Dr. Schiötz' criticism of my apparatus and why we failed to get the same results as Schiötz. I granted this request and it was over five months after Dr. Schiötz received the tonometer and letter that he replied. In his reply he failed to criticize the apparatus and the method of testing, which was the sole object of Dr. Marple's letter. The only remark relative to the testing he made in the letter was "Dr. McLean evidently has values different from mine. I do not understand why."

I constructed the scale from an average of over 100 tests using several tonometers. According to my tests the normal intraocular pressure with the McLean tonometer has for its lower limit 22 mm. and its upper limit not above 40 mm. An upper limit of 40 mm. may be too high for some eyes. I have seen plenty of normal cases registering as high as 40; yet I have found eyes registering not above 36 mm. where there were evidences of glaucoma. On those cases I have tried the Schiötz tonometer also, and have been able to get readings as low as 22 mm. Schiötz.

Since the experiment on the first human case I have had the privilege of two other human cases, the results of which are cited in the article.

According to the literature I could find, Weber and Wahlfors are the only other men making direct manometer experiments on the living human eye in situ. I could not find any record of Weber's conclusions. Wahlfors' test (26 mm.), which he determined to be the normal intraocular tension of that case, is above Schiötz' upper limit, but it is quite within what I have found to be the limits.

At the time I was about to read the paper at the Academy of Medicine, the chairman of the section asked if I would have a physicist go over my apparatus with the purpose of taking part in the discussion. I could not get the Columbia professor because of his absence on Sabbatical leave. I did, however, secure Prof Green of the Boys' High School. He looked over my apparatus, then requested me to demonstrate the apparatus and use both the Schiötz and McLean tonometers. He made notes of his observations and reported the same in the discussion.

Unfortunately they had no stenographer present at that meeting and the report as given in the Archives is only what the secretary had in his notes of the meeting.

FLUCTUATIONS OF REFRACTION IN DEVELOPING CATARACT.

CHARLES ZIMMERMANN, M D., F. A. C. S.

MILWAUKEE, WISCONSIN.

This paper discusses the physiologic and pathologic changes of the crystalline lens in their influence upon refraction, illustrated by a case of developing cataract observed for many years. It was read before the Wisconsin State Medical Society, October 3rd, 1918.

The important part which the crystalline lens normally plays in the refraction of the eye makes it easily conceivable that certain changes of the lens must lead to alterations of refraction. These changes are physiologic and pathologic. The physiologic changes are a natural accompaniment of the growth (with the advancing years in the course of life) of the individual, and are of great interest for the understanding of the pathology of the lens. Most important are the alterations of the dimensions and shape, consistency, and coloration of the lens. During the whole of life new lens fibers are formed from cells at the meridianal rows of the equator of the lens, so that its volume and weight increase, from the twenty-fifth to the sixty-fifth year by one-third, its diameter by one-tenth. (Priestley Smith.[1])

The increase of the volume by this new formation of fibers preponderates over the apparent simultaneous loss of the water content of the lens which produces changes of the nucleus. In consequence of the larger volume of the lens the anterior chamber of older people generally is markedly more shallow. The growth of the lens influences its shape, from the almost spherical form of the lens, if left to itself, of the newborn, to the less curved anterior surface of the senile lens, whose sagittal diameter is smaller than its equatorial diameter. Perhaps the acquired hyperopia at higher age is due to this flattening of the anterior surface of the lens.

Physiologic alterations of consistency are due to sclerosis of the lens, a process which may be compared with the cornification of the epithelium. It is characterized at first by a gradually greater hardness of the more centrally located lens fibers from loss of water. A cross section of the senile lens frequently shows the nucleus dry without luster, the cortex moist and glistening. Hess[2] found in some cases the whole nuclear portion converted into a homogeneous mass, in which no single fibers were visible. The sclerosis increases the refractive index. Halben[3] showed that loss of water alone increases the refractive index of the lens. Whether the higher index in sclerosis is due only to loss of water or also to chemical alterations of the nucleus, e. g., the greater amount of the more refracting cholesterin (Jacobson, Matthiesen), is still uncertain. The nucleus seems to grow with advancing age by supplanting the soft cortex. If this is excessive, it may develop into brunescent cataract, whose brown color differs from the normal senile lens only in degree, not in kind.

Probably in consequence of abnormal loss of water another pathologic condition with apparently normal shape of the lens is created, viz., an abnormally great difference between the central and peripheral parts of the lens which may amount to a difference in refraction of from 10 to 16 diopters. Sometimes the turning of the ophthalmoscopic mirror in such cases shows a migration of the illuminated field in the central parts opposite to that in the peripheral parts. The center of the pupil may appear less bright than the periphery, and the border between them may be indicated by a dark shadow in form of a crescent or a ring. The ophthalmoscopic examination thru the central area of the pupil may reveal more or less high myopia and thru the peripheral area a lower degree of myopia, emmetropia, or hypermetropia. From the similarity of these phenomena with those of true lenticonus, Demicheri[4] termed them spurious lenticonus.

They occur in perfectly clear lenses or in lenses that may remain clear for a long time, but also as precursors of, or in combination with, cataract.

Vision may be considerably reduced, so that extraction is indicated, but in some cases it may be improved by correction of the nuclear myopia. Hess showed that from the 25th year with advancing age the difference between the index of the nucleus and that of the adjoining cortex constantly increases. The refraction of rays at the surface of the nucleus, at equal difference of index, must be the greater the greater the curvature of this surface. As the difference of index at higher age, in which this phenomenon exclusively occurs, is considerable, relatively slight differences in the curvature of the nucleus could essentially influence the refraction. Altho these differences of shape of the surface of the nucleus have so far not been exactly investigated, Hess considers their possibility, a priori, as not too remote to serve in the explanation of the phenomenon.

Another disease of the lens without opacity consists in the formation of radial clefts immediately under the capsule, which may remain transparent for a long time. They may be invisible in certain positions of the ophthalmoscope, but on slightly tilting the mirror may shine with a lustre and again appear as darker streaks. Vision may be more or less impaired, and the patient may complain of polyopia and metamorphopsia due to development of lenticular astigmatism. Gradually the contents of these clefts may become opaque and produce cataract. The affection resembles the first stage of naphthalin poisoning of the rabbit, in which Hess showed that the cataract is preceded by the formation of spokes clear as glass. In this stage, volume and weight of the lens are regularly increased. Becker[5] considered the fine, totally reflecting clefts in the deeper strata of the cortex as the first symptom perceptible during life of incipient senile cataract. Hess, however, proved that these clefts do not lie in the deeper strata of the cortex, but closely under the capsule. He considers this proof important for the understanding of the development of cataract. As is well known, the most frequent form of senile cataract is the subcapsular cortical cataract.

With regard to pathologic alterations of the epithelium Hess examined a large series of eyes affected with various kinds of cataract. The only changes which he could find with certainty in the great majority of these eyes with senile opacities, consisted in more or less numerous irregularly bordered, vesicular vacuoles, of which he could not say whether they lay between epithelium and capsule, or closely under the epithelium, between this and the cortical fibers. He never found them in eyes with perfectly transparent lenses, but especially in comparatively early stages of subcapsular cataract, sometimes scarce, sometimes in such quantities that they gave the appearance of fine vesicular foam immediately under the capsule. He thinks that they cannot be due to anything else but accumulation of small quantities of clear fluid under the capsule, or the epithelium.

Likewise with regard to the occurrence of clear clefts previous to the development of supranuclear cataract, Hess describes a visibly not opaque lens, in which he found a bright reflecting line parallel to the equator between cortex and nucleus, composed of numerous minute clear formations, and also a large number of finest fissures between the apparently normal fibers of the most peripheral layers of the nucleus. It gave the impression as if clear fluid had accumulated in very small quantities in these formations. Hess believes that at the beginning of cataract an intussusception of fluid takes place with the microscopically demonstrated destruction of the epithelial cells, to which he attributes the pathogenesis of subcapsular cataract and the young cortical fibers, which not only anatomically but also in their biologic properties are the more related to the capsular epithelium the younger they are.

To this corresponds the increase of volume of the lens in incipient cataract,

evidenced by the greater shallowness of the anterior chamber, as also found experimentally in the first stages of naphthalin cataract. Several cases were attributed to this stage of intumescence of the lens in which, in predisposed eyes, glaucoma was brought on by swelling of the lens. The myopia preceding or accompanying the formation of cataract has been ascribed to these changes. By intussusception of water into the cortex its index will be lowered and thereby the total index increased, and also the curvature of the lens may be increased.

In the progress of cataract to maturity the lens gives out fluid to the surroundings. Its volume and weight decrease and with this the depth of the anterior chamber becomes again normal, with decrease of refraction.

As an illustration of the refractive changes due to pathologic alterations of the lens, I should like to report one of a number of cases which I had under observation for many years:

An otherwise healthy, strong man showed, when first examined at the age of 52, emmetropia, and presbyopia. In his 64th year his sight became impaired. He had developed myopia and incipient cataract, at the peripheral cortex of both eyes. Vision was corrected by R. —3.50, L. —1.00, for reading R. —1.50, L +0.75. At 65, V. R. 20/200, V. L. 20/100. His myopia had increased and was complicated by astigmatism. The ophthalmometer showed R. —1.00 180°, L. —0.75 180°. V. was corrected with R. —5.00 ⌒ —0.50 cyl. 90° to 20/30, L. —1.00 ⌒ —2.00 cyl. 90° to 20/20. For reading R. —3.50 ⌒ —0.50 cyl. 90°, L. —1.00 cyl. 90°.

In certain positions of the opthalmoscope the fundus of each eye was clearly visible, in others not, on account of sclerosis of the nucleus of the lens. The peripheral opaque spokes had not much changed. The anterior chamber was shallow. There was monocular polyopia.

In each of the following years the spheres and cylinders had to be increased, vision gradually decreasing even under correction. At the age of 70 he received the maximum, viz.: R. —10.00 ⌒ —2.00 cyl. 90°, V. = 20/100, L. —6.00 ⌒ —4.50 cyl. 90°, V. = 20/50. At 72 V. with these glasses was the same. V. without glasses was fingers at 6 feet.

The ophthalmoscopic examination revealed R. clear red reflex, dimmed in the center by the sclerotic nucleus, details visible, no changes of the retina. Cataract not progressed. Left Eye: The same picture of sclerosis with slight opacities at the equator. Sugar was found in the urine for the first time, but there were no other diabetic symptoms. It certainly had nothing to do with the affection of the lens.

At 75, details of fundus could be seen in left eye, not in the right. The sclerosis of the nucleus had increased. The swelling of the lens had decreased as indicated by the less shallow anterior chamber, and also refraction, which was now: R. —9.00 ⌒ —1.00 cyl. 90°, V. = 20/100, L. —6.00 ⌒ —3.75 cyl. 90°, V. = 20/50, i. e., vision had remained the same. It had not changed in the next four years, but myopia and astigmatism at 79 had further decreased to R. —7.00, V. = 20/100, L. —5.00 ⌒ —2.00 cyl. 90°, V. = 20/50.

At 81 V. with these glasses was, R. 20/200, a little less, V. L. 20/70. The ophthalmoscope showed R. faint red reflex, some opaque cortex on temporal side, clear on nasal side, nucleus opaque. Left: Cortex pretty clear except a few spokes, nucleus diffusely opaque, but details of fundus faintly visible. With R. —2.50 he reads large print; with L. —2.00 cyl. 90°, No. 1 Jaeger at 6 inches, No. 2 at 9 inches, and No. 4 at 11 inches. The patient was a very assiduous reader, and read with these glasses for many hours every day without discomfort.

THE NONOPERATIVE TREATMENT OF SENILE CATARACT.

A. S. Green, M. D., and L. D. Green, M. D.

SAN FRANCISCO, CAL.

This paper considers the etiology and forms of partial senile cataract, describes the method of treatment for it, and gives in statistics results obtained.

Senile cataract is a condition which concerns a very large proportion of the human race. While apparently more common among certain peoples than others, none are exempt. It may almost be regarded as an accompaniment of old age just as is gray hair.

One observer has found that opacification of the crystalline lens of greater or lesser degree is present in over 90 per cent of all people past the age of sixty-five. Among white races it occurs frequently as early as forty.

When opacification has begun, its rate of progress is very uncertain. A cataract may become mature in two or three months or it may remain immature for thirty-five years or more. Failing sight of old age, not correctible by glasses, is very often due to this condition. Fortunately this opacification usually takes place at the periphery of the lens, beyond the pupillary area, and thus does not generally interfere with vision. However, the pupillary region is involved with sufficient frequency to reduce the acuteness of vision in many elderly people.

Etiology.—Aside from the cataracts occurring in general diseases as in diabetes, or those following the ingestion of poisons as naphthalin, ergot, etc., and that which is frequent among certain vocations as in glass blowing, we know very little of its etiology. Neither do we know much about its prophylaxis. The question that interests us is: Can the progress of opacification of the crystalline lens be checked or prevented? The attitude of ophthalmologists generally has been that the condition must go on to maturity and the cataract then be removed surgically.

While it is absolutely unnecessary to allow a patient to await the blindness that comes with a mature cataract before resorting to operative intervention, it is also a mistake to operate before the development has reached such a stage as to interfere with business or pleasure. Roughly that stage is reached when vision has fallen to 50 per cent. When it has been reduced to less than 50 per cent there is no need to temporize further, and the cataract should be removed surgically. It is, however, before a loss of 50 per cent has occurred that nonoperative measures should be used to avoid subjecting the patient to an indefinite period of worry and impaired efficiency.

Many remedies have been suggested for the arrest or absorption of cataracts. But it has remained for Col. Henry Smith of Amritsar, India, to put the nonoperative treatment on a more definite basis. By that method in over 80 per cent of our cases, the opacification has been checked or the vision improved. But to obtain these results the treatment must be begun before vision has fallen to half of normal, and carried out in detail. The earlier the treatment is instituted the better the result. The permanency of the treatment is, however, uncertain. With some patients the improvement lasts only a few months, with others the improvement has remained after a period of over four years, the time when we first commenced this treatment. But if this particular treatment does not improve the vision it can do no harm as there is practically no danger from this procedure. We have not had a single deleterious result. Should an operation for cataract be necessary later it is probably an advantage to have had this treatment previously because of the apparent general improvement in eyes following this treatment. The greatest objection that may be raised is the severe pain often produced which may last for several hours.

Type of Cataract and Histologic Changes.—The type of cataract which

best responds to this treatment is the simple, uncomplicated senile with radial or diffuse opacification. Dense nuclear or subcapsular cataracts will not be affected materially by this treatment. The pupil should be first dilated in order to exclude retinal changes, especially the senile macular degenerations. These will often account for failure to obtain improvement in vision for which the treatment would otherwise be blamed.

Ophthalmoscopic examination of the lens after treatment will show little apparent change in spite of the improvement in vision as only the finest opacities seem to be affected rather than the larger ones.

Method of Procedure.—The patient should be in a bed in a hospital. Near the bed, within easy reach, should be an electric stove with a basin of hot boric solution for compresses. The eye is anesthetized with three drops of 4 per cent cocain solution instilled at intervals of five minutes. Twenty mm. of 1-4000 cyanide of mercury solution is drawn into a freshly sterilized glass syringe with a small needle. To this 2 mm. of sterile 4 per cent cocain is added. The needle is then inserted under the conjunctiva just below the external rectus and about 1 cm. from the limbus in an area free from blood vessels, and the solution slowly injected. A large bleb of conjunctiva is raised. The hot compresses are applied at once and maintained as long as the patient has pain. It is about the only thing that gives relief. A hypodermic of morphin may be necessary. The eye is compressed three times daily for three or four days afterwards.

The treatment as described above is that as given by Col. Smith. In addition to this the writers have found it of great value to institute auxilliary treatment that is carried out by the patient at home, over a period of from four to six months. One week after the injection the patient is given a 1 per cent solution of K. I. which is to be used as an eye bath in an eye cup for five minutes every morning, and every other night. On the alternate night the patient puts one drop of 2 per cent dionin in the eye. The strength of the dionin is increased 2 per cent each month until an 8 per cent solution is used. This method of using dionin and K. I. has been highly lauded by other writers, and used in connection with the Smith treatment we have found it very satisfactory.

The injection is given only once. Whether repeating the injection would be beneficial we are not prepared to say as we have not tried it.

The results given below were those obtained in private practice, and included 72 eyes.

	Cases	Per cent
Improved	42	58.5
Arrested	18	25
Cataract progressed ...	12	16.5

The degree of improvement in vision ranged from 11 per cent to 150 per cent. In twenty-five cases or 36 per cent of those injected, there was an improvement in vision of 11 to 40 per cent.

In sixteen cases or 22 per cent of those injected there was an improvement in vision of 50 per cent or better.

The period of observation ranged from a few weeks to four and one-half years.

The vision a day or two after injection is usually lower than just prior to injection, but improves very rapidly thereafter and reaches its maximum about one week after. The conjunctiva becomes greatly swollen so that it may protrude between the lids for a few days. The redness persists for three or four weeks. After this the eyes feel "stronger" and the patient reads and sews with much more comfort than before.

Conclusion. From our experience and the observation of others who have given the treatment a thoro trial, this method has been a decided help in conserving vision at a time of life when even a few months or years of sight is worthy of consideration.

NOTES, CASES AND INSTRUMENTS

OPTOTYPE FOR YOUNG CHILDREN.

JOHN N. EVANS, M. D.

BROOKLYN, N. Y.

We have all experienced the difficulties arising in taking the vision of young children from the so-called kindergarten test-charts. The very obvious failings of these, suggested this attempt to provide a system which will be at once practical and efficient.

In a review of the literature it was surprising how little careful work had been done along these lines. Such charts as are in common use—those of Reber, Seitz, Ettles, Wolffberg, Thorington, etc., represent fairly well the entire field, the most pronounced faults being in the selection of the characters:

1. Which are made in silhouette, line, shading and combination of these.
2. The names of which may easily be confused.
3. Employing a multiplicity of characters.
4 Which are markedly inaccurate as a measure of visual acuity.
5. Representing objects unfamiliar to the young child.

One factor which seems to have been neglected by many authors is the one of the child's physical condition. The charts are stated to be arranged for children and illiterates but it will be noted that they often present figures far beyond the child's comprehension. Surely we need the help of what little understanding the child has. Illiterates may be either mentally deficient or of normal adult mind, and the chart if constructed to reach the young child, can be followed by them, but not the reverse. With this in mind it seems fair to allow 50 per cent to favor the child's mentality and the other half to gain the visual acuity.

From a study of the statistics we find that the average child in the public schools of Greater New York does not know his letters in a dependable way until he can read, nearly the age of seven and a half, and though he may know his numbers slightly under this age, at six and a half years, he is likely to give unsatisfactory answers at the time of testing. In New York City the child enters kindergarten at the age of five, and elementary school at the age of six, so that these are the ones we need most to reach when the relatively heavy work takes its first toll.

In the construction of characters for a chart certain principles are to be followed:

1. The characters are to conform as nearly as possible to the international standard, particularly in structural and visual value.
2. A circle, or ring is to be used to form the body-structure on which the characters are built.
3. One-minute projections or interruptions of the body are to measure the capacity to perceive and recognize the individual characters.
4. There are to be few characters, as the child's vocabulary and concentrating ability are not to be overtaxed.
5. The characters are to be familiar to a child three or four years old.

In going over many characters used in kindergarten work, and in studying drawings made by small children, particular note was made of those which attracted the young child most and which he reproduced most successfully. After trying many of these it was found impossible to construct test characters from most of them, using a one-minute line and maintaining the five-minute size object. When finished most of them were so out of proportion as to be hard to recognize, or they formed undesirable black masses.

Those finally employed were:

1. *The Circle.* This is simply the body on which the others are built. It subtends an angle of five minutes, the rim is of one-minute width.
2. *The Cat's Head.* The circle forms the body of the character and each ear represents a one-minute mass. The features were made small so that the lower figures would not appear gray at six meters distance.

3. *The Man's Head*, built on the same circle is distinguished from the cat and other characters, merely by recognizing that the projections are at the sides, thus forming a hat-brim. The crown is formed by an arc of short radius. The brim is formed by one-minute masses.

4. *The Apple* is recognized by its stem which projects one minute above the rim of the circle and is the same in width.

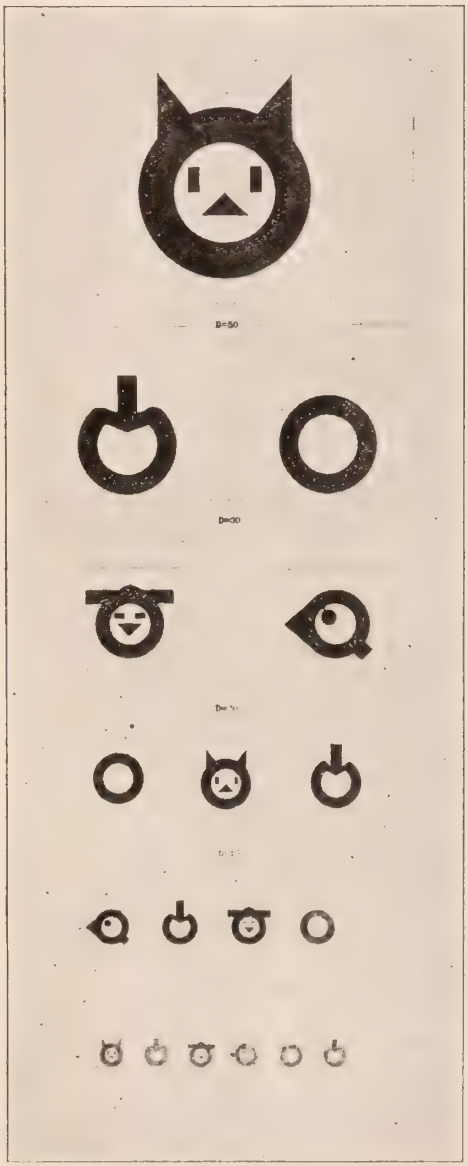

Fig. 1. Optotype for Young Children (Evans).

5. *The Bird's Head* is formed on the circle by adding a one-minute mass for a bill and another for a neck. The latter, as well as the eccentrically placed eye, seem necessary to make the picture complete to the child.

Much develops in the use of the chart which is of interest to the psychologist.

There are many names by which the other characters are called: Cat, fox, tiger, etc., man, monkey, pumpkin, etc., apple, cherry, plum, etc., bird, chicken, bird's eye, etc., circle, hoop, wheel, ring, etc.

Some of the advantages of this test-chart are:

1. The chart has given good results with children as young as three years.
2. It can be used with ease in dispensary and office work.
3. It is not necessary to describe or point to locate the one-minute section, naming the character is proof that it is seen.
4. It requires only simple direct answers.
5. The names of characters are not easily confused with each other.
6. There are many names for each character, allowing the child to answer quickly and not overtaxing its small store of names.
7. The figures are such as have been learned in the child's own experience and represent very familiar objects, as he himself draws them.
8. It is a very satisfactory test for any illiterate.
9. It may be used with mirrors.
10. It supplies a practical "one-minute" test.

INDICATIONS FOR OPERATION IN UNILATERAL CATARACT

Dr. Francisco M. Fernandez.

HAVANA, CUBA.

What should be the attitude of the ophthalmologist towards those frequent cases of unilateral cataract?

This subject has been debated and some authorized opinions have been

given in favor and against surgical intervention.

There are really many cases in which the opacity of the lens affects only one eye, while the other eye remains with a degree of vision normal or nearly so, but before giving our opinion about our way of thinking in these cases, we believe that they should be grouped according to their age.

The traumatic or congenital cataracts of children and early youth have often a hard nucleus and although they are rarely unilateral, and most commonly occur in both eyes, one should consider what to do in unilateral cases. In traumatic cases, which are as a rule unilateral, when there is no rapid spontaneous absorption, which so often happens, one should operate, after waiting for some time for the spontaneous absorption to occur[1]. Otherwise, if the cases are left unoperated, in many of them there may occur a strabismus more or less defined, due to the lack of control upon the affected eye and the disturbance of the normal binocular vision. With the operation, strabismus can usually be avoided.

Not all the cataracts of early youth are hard and it could be said that most cases are not, but it is convenient in all cases to operate by any of the different procedures in use. The one we generally follow is that followed by our worthy teacher[2] which consists in the discission or needling operation. We do not make use of the extraction method in order to avoid disagreeable complications, and in children one can practice a series of discissions without any of the dangers that may arise after a simple extraction. This method is also more easy to follow in children.

After the first 20 years of life, these cases vary in the treatment to be followed. Now we do not have to treat with the soft cataracts of children and youth, and the semisolid and hard cases are more frequent. The operative indications are not so imperative as in the previous series, but operation should be done in all traumatic cases, even after waiting some time for the absorption to occur. Even considering the operated eye, nonuseful from the standpoint of vision, on account of the high refraction of this eye as compared with the normal in the other eye, it is always a source of reserve to be used in a possible loss of the other eye, especially when the patient's occupation is a hazardous one.

The operated eye is really a reserve strength, and could be used only with a strong glass, but as this often produces some mortification to the patient, he ends by not using any correcting glass. This does not mean that the eye is worthless, and although there is no binocular vision, on account of the difference in refraction between the eyes, the operated eye can be used at times.

Concerning the esthetic effect, we agree with Zbikowski[3] that many people consider it a disagreeable thing to have a white pupillary space, as is the appearance in the affected eye, as compared with the normal black appearance of the pupil in the sound eye. This fact may be taken as another indication for operation in young people.

In old people, or people over 40 years old, the chief indication for operation in senile cataract should be the possibility of the other eye becoming affected and that the patient may become blind in both eyes at the same time. Another indication is when an over-ripe cataract may give rise to symptoms as of a foreign body in the eye and afterwards cause a secondary glaucoma.

What we have mentioned is in relation to cases of senile or uncomplicated cataract, but there is another group of cases in which the cataract is not senile, without being traumatic. We refer to some cases of cataract due to local affections like iritis, keratitis, and the like, and those due to some general disease like diabetes. In this group of cases our usual conduct is to refrain from operation in order to avoid unnecessary complications, but there are some cases in which an operation is indicated we do so by means of the combined extraction method.

DIFFERENTIAL MYDRIASIS. ATROPIN, COCAIN AND EUPHTHALMIN.

GEORGE C. ALBRIGHT, M. D.

IOWA CITY, IOWA.

It would seem that so common a subject as mydriasis and the action of the various mydriatics would be unable to furnish anything of interest. However, there has come under my observation a case in which the reaction of the pupils to the different mydriatics was so marked that it led me to an investigation of the literature on this subject. The scarcity of reported cases and the absence of comment on the different mydriatics would lead one to believe that the subject is not so common as at first supposed.

Mydriatics fall into two groups; those which produce mydriasis by paralysis of the myoneural junction of the sphincter pupillae, and those which produce their effect by stimulation of the dilatator fibers. Atropin and euphthalmin are examples of the first group, while cocain represents the second group. Both groups act locally (Roemer[1]). Cushny[2] points out this differential action very clearly.

It is an old saying that atropin paralyses the sphincter, while cocain stimulates the dilatator fibers. According to de Schweinitz[3] the existence of a dilatator muscle in the iris is denied by some authors, but the combined anatomic and physiologic evidence of its presence seems to be conclusive. All agree that there is a definite myotic tract and a definite mydriatic tract. It is also accepted that atropin acts upon the myotic tract, and that cocain acts on the mydriatic tract.

There may be also a marked difference observable in the reaction of the pupil of different individuals at various ages. As a rule (Jackson, personal communication) elderly people respond better to cocain than to atropin. In children the reverse is true. A few cases have been observed in which there is no mydriasis, following the use of atropin in adults.

The case which I wish to report is one in which there was a marked difference in the reaction of the pupil to atropin and to cocain; the former producing only slight mydriasis, the latter producing prompt, full mydriasis. The action of euphthalmin was also tested independently and found to be practically the same as that of atropin. I might note here that all the drugs used were fresh and that their therapeutic action was tested by direct comparison in the eyes of several other patients.

Mr. D., aged 54, laborer, consulted me January 2nd, 1917, for eye trouble which began about three months previous, when he was struck in the right eye by a piece of flying stone. There was some pain, no dimness of vision. The next day the eye felt fairly well. About one month later there began to be dimness of vision which gradually increased until now he sees only large objects. There is no previous trouble in the right eye; left eye, no history of trouble.

Examination showed right vision 6/60, corrected with myopic correction to 6/10; left vision, 6/6. Near vision, right J 12 corrected to J 1 at 22 to 28 cm.; left, J 6 corrected to J 1 at 22 to 48 cm. No muscle error, no ciliary injection, no conjunctival inflammation, no plus tension. Cocain 5 per cent, euphthalmin 5 per cent instilled in each eye. Pupils did not dilate well. Right fundus, fine floating opacities in the vitreous, no cataract, no evidence of glaucoma, no conus. Left fundus, negative. There was a badly deflected septum. Sinus examination was practically negative except for a slight amount of pus in each antrum. A diagnosis of uveitis, right, was made. The patient was put in the hospital on pilo-

carpin sweats. Locally atropin 1 per cent, dionin 5 per cent, were used; the pupils would not dilate. The atropin was increased gradually, even using powdered atropin, until signs of toxicity developed, the patient growing irrational, but still no dilation. The blood Wassermann was negative, none made on the spinal fluid. There was a marked local and general reaction to 1 mg. of O. T., and to 3 mg. of O. T. The patient observed that his vision was better after each injection of tuberculin The opacities were fewer, apparently. The vision was not tested.

January 8th, 1917, against advice he left the hospital. He came to my office, where the size of the pupils, 4 mm., was noted and cocain 5 per cent, and euphthalmin 5 per cent again instilled. Much to my surprise the pupils dilated to 7 mm. each, and I requested the patient to return to the hospital that the internes might observe the dilatation secured by cocain which we had been unable to secure with atropin.

From January 8th, 1917, to January 30th, 1917, I made numerous attempts to secure mydriasis with atropin and also with cocain. The results obtained were uniform with the first results above noted and were observed by several other physicians. It is worth noting that cocain each time produced good, prompt mydriasis. If instilled when the pupils were under the effect of atropin, mydriasis was secured a little wider than when not under the influence of atropin. When euphthalmin was used alone, mydriasis was secured between 4 and 5 mm.

Summing up my observations of the case; first, there was no mydriasis, either eye, secured by atropin carefully applied, pupils 3 to 4 mm.; second, euphthalmin alone secured some mydriasis, 4 to 5 mm.; third, cocain alone produced prompt mydriasis, 6 to 7 mm.; fourth, cocain, 5 per cent, and euphthalmin, 5 per cent, secured prompt mydriasis; fifth, cocain in the atropinized eye secured widest mydriasis, 7 mm.

Although having no bearing directly upon the subject, the patient's vision when he passed from under observation, January 30th, 1917, was unimproved but was as good as when first seen; 6/12 right, 6/6 left with correction. Repeated efforts to locate him since have failed.

UNILATERAL OPTIC NEURITIS.

CLARENCE A. VEASEY, M. D., F. A. C. S.

SPOKANE, WASHINGTON.

Two isolated cases are recorded below because it is believed there are some points of unusual interest pertaining to each.

CASE 1. *Unilateral optic neuritis following the extraction of senile cataract.* D. J. B., aged about sixty, was first seen February 18th, 1913. There was a macula in the center of the left cornea which, according to the patient, had been present since an attack of scarlet fever in childhood. The lens was cataractous and mature. Light perception and light projection were good. In the right eye the lens contained numerous opacities, but the cataract was not yet mature.

Extraction of cataract from the left eye was advised, the probability of the macula interfering to a considerable extent with the central visual acuity subsequently explained, and on July 3rd, 1913, the operation was performed by the combined method without complications. After healing the patient was glassed, obtaining 6/22 vision, but unable to read ordinary type because of the corneal macula.

On March 14, 1914, the cataract in the right eye being mature, it was extracted by the combined method. Patient was quite nervous during the operation and a small amount of vitreous was lost. Convalescence was uneventful, there being no further complications. On April 21st following, the thickened capsule was needled at the hospital. There was no complica-

tion and the patient read with glasses Jaeger 2, having 6/12 vision.

On May 14th, about three weeks later, the patient presented himself at the office, stating that he was unable to read the small type any longer. Examination showed a good opening in the capsule, the media clear, but the patient could read only Jaeger 6, and it was impossible to improve the vision beyond this amount. Further examination revealed what was apparently a swelling of the optic disc. Never having had the opportunity to observe a case of optic neuritis in an eye from which the lens had been extracted, it was rather difficult to determine whether the rounded edge of the disc was normal or pathologic. In two weeks more, however, there was absolutely no doubt, distinct optic neuritis being present. Vision which had been 6/12 with glasses was reduced to 6/45, and could not be improved.

Examination of the urine was negative as to albumin and sugar, but the patient was passing a somewhat smaller amount than normal. No blood examination was made. Examination of the nasal accessory sinuses was also negative. As this was before the time we were looking for focal infections, his tonsils and his teeth were not examined.

The fundus of the other eye could be distinctly seen, notwithstanding the macula, and there were no changes either in the media or in the optic nerve.

The patient was given the usual sweating treatment, together with mercury and the iodides, and on November 2nd, 1914, the swelling of the optic nerve had entirely subsided, and with glasses he could read with the right eye Jaeger 3, and his distant vision equalled 6/12.

It must be rather unusual to have an optic neuritis follow the extraction of senile cataract, either as a complication or coincidence, and the case is reported for that reason.

Case 2. *Unilateral optic neuritis following a blow on the frontal region.* Mrs. A. H. M., a married woman, who had enjoyed apparently good health, consulted me September 4th, 1909. She stated that three weeks before she had received a severe blow on the forehead about three inches above the right eye. No disturbance of any kind was observed for two weeks, but about one week before presenting herself for examination she noticed considerable fogginess in the vision of the right eye. Two days before she was first seen only light perception remained. The vision was, for R., L. P., and for L. 5/5.

Examination of R. showed a marked and extensive optic neuritis, the edges of the disc being everywhere blurred, no hemorrhages being present. The media and fundus of the left eye were normal.

The patient's nasal accessory sinuses transilluminated well, there was no free pus in the nares and no indication of any sinus disease. No crepitus could be elicited.

She was given mercurial inunctions and rapidly increasing doses of iodid of sodium. In a few days' time the vision began to improve. On October 16th, 1909, the swelling of the nerve head had so subsided that the nerve was distinctly pale, and injections of strychnia into the temple were employed. On December 3rd, 1909, there was distinct optic nerve atrophy, so far as the pallor of the nerve head was concerned; but the vision for the right eye equalled 5/6+ and remained so until the patient passed from observation which was some months later.

It is believed that in this case the blow on the frontal region, altho a considerable distance above the orbital cavity, produced a periostitis or some other disturbance at the apex of the orbit which in turn gave rise to the optic neuritis. The patient having only light perception at the time of presenting herself for treatment and 5/6+ at the time treatment was discontinued is to be considered exceedingly fortunate.

SOCIETY PROCEEDINGS

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

Annual Congress held in London, May 1st, 2nd and 3rd.

President, Mr. J. B. Story, Dublin.

The President expressed his high appreciation of the honor conferred upon him by his colleagues, in electing him to fill the chair of the Congress. The Society, he said, was much indebted to its past Presidents, and to none more than Mr. Treacher Collins, who steered the bark of their fortunes through the stormy weather of the last years of war. It was largely due to him that the last Congress was such a success.

On that occasion the discussion on plastic surgery of the eyelids excited very great interest, and the exhibition of cases, photographs and casts made a deep impression on those privileged to attend the meeting, or who visited the Plastic Hospital at Sidcup. The same subject had been chosen by the Bowman Lecturer this year, Professor Morax. The discussion also on Contagious Diseases of the Conjunctiva, held at Swanley, was also a pleasant and important feature of last year's Congress.

He also expressed satisfaction that the Oxford Ophthalmological Society and the Midland Ophthalmological Society had become affiliated with the larger body. He was now happy to state that three other societies had also been affiliated: the North of England, the Egyptian, and the Irish.

Among the deaths during the past year, he wished to specially mention four, two of them Original Members—Dr. John Couper and Dr. Thomas Buzzard, Mr. Devereux Marshall had died in Bombay on active service, of cholera. He believed Mr. Marshall was at one time Secretary of the Society, and he had served on its Council. Another whose name he would mention was Sir James Mackenzie Davidson, whose work on the localisation of foreign bodies in the eye by means of X-rays was familiar to all. He concluded by a reference to the special subjects for discussion at the present Congress.

On the initiative of Sir Anderson Critchett, the President was cordially thanked for his address.

Abiotrophy of Retinal Neuro-Epithelium.

Mr. Treacher Collins read a paper on Abiotrophy of the Retinal Neuro-epithelium, or *"Retinitis Pigmentosa."* He pointed out that the pathologic examination of several eyes with retinitis pigmentosa had shown that the affection might occur without sclerosis of the choroidal blood vessels, and that the primary change appeared to be a degeneration of the rods and cones. As the condition is hereditary, he suggested that the degeneration might most aptly be described as an abiotrophy. From this standpoint, its various accompaniments might be explained as follows:

The increase in the neuroglia of the retina is similar to that met with in various forms of neuronic abiotrophy, and not like what occurs in sclerosis where there is an increased firmness in consistency. Secondly, the pigmentation of the retina is caused by the degeneration of the rods and cones, together with their attached nuclei, leaving spaces in the membrana limitans externa, through which the pigment epithelial cells, or their pigment granules, can migrate. Such migration he considered was probably due to the physiologic capacity for movement in the direction of light, which these cells and granules possess.

The light-coloured dots sometimes seen in the retina, and the hyaline nodules occasionally met with on the optic disc, are of the same nature; and are due to hyalin degeneration of cells derived from the outer layer of the secondary optic vesicle, from the pigment epithelium overlying the choroid, and

the neuroglia in the optic papilla. In typical cases the degeneration of the neuroepithelium commences where it is first fully developed. Around the macula, which, being last developed, is last involved. This is why sight begins to fail in the form of a ring scotoma.

Night blindness, the earliest symptom, is due to the failure of vision commencing in the part of the retina which, in the dark-adapted eye, is the most sensitive to light, that is 10° to 20° from the fovea. Typical cases of retinitis pigmentosa occur in which the macula alone is involved. There being no blood vessels at the macula, there are, in these cases, no branching pigment patches, only scattered dots and granules of pigment. The deafness and affections of the nervous system met with in association with retinitis pigmentosa are also due to abiotrophy.

Discussion: Professor Herbert Parsons remarked on the danger of labeling a diseased condition with a particular term, and considering that this explained it. Even if it were an abiotrophy, one had to get behind that and try to ascertain the causation. He did not think it would be difficult to oppose arguments to each thesis set up by the author, if there were time.

Sir Anderson Critchett spoke of the way subjects of retinitis pigmentosa were helped by wearing yellow glasses. He asked whether members had had experience with Crookes glasses (which take out the purple rays) for this condition. The subject was also discussed by Mr. R. Greeves and Mr. M. S. Mayou.

Sclerectomy for Glaucoma.

Mr. George Young read a paper on results of double sclerectomy operation for glaucoma. The paper was founded on 12 cases. The reduction in tension had been, so far, permanent: there had been no bad results over periods of several months to two years. The incision must be as near the limbus as possible, and he emphasized the necessity of making a second opening. The operation which he described could now be done on cases of acute glaucoma. It was not disfiguring and there were no relapses. The President considered the operation easy compared with other procedures.

Glaucoma Operations.

Lieut.-Col. Herbert contributed a paper on the future glaucoma operation. He said that in India cases of glaucoma were always far advanced when seen, and he had been driven back to the iris prolapse operation. An incision was made by puncture and counter-puncture, with a 1 mm. Graefe knife: the incision was entirely subconjunctival. In advanced glaucoma the incision could be safely made of almost any size. This operation was free from the disasters which might attend iridectomy for the condition. The whole operation could be performed without emptying the anterior chamber, and its chief feature was the sufficient widening of the filtration area. He described the technic in minute detail.

Contracted Sockets.

Mr. R. R. Cruise read a paper on contracted sockets in which he described a procedure to enable a socket which had been disorganized by injury to hold a glass eye.

Discussion: Mr. C. Higgens showed a number of soldiers on whom he had performed various operations for the same purpose, and demonstrated the procedure followed in each case.

Mr. W. Sinclair discussed Eye Complications in Cerebro-spinal Meningitis, and Mr. Percival J. Hay read a paper describing some new test-types.

VISUAL REQUIREMENTS OF AVIATORS.

On Thursday afternoon members assembled at the Psychological Laboratory, University College, where a discussion was held on the subject of Visual Requirements of Aviators.

Stereoscopic Vision.

Professor Spearman delivered an address on stereoscopic vision, which had been decided by many people, in-

cluding Americans, to be the most important factor in the visual fitness of aviators, especially in regard to successful landings, a source of much mortality among fliers. He divided his remarks into (1) a method of testing stereoscopic vision in candidates, (2) suggestions as to means of improving the vision of aviators.

This faculty had to be differentiated from quasistereopsis or the power of appreciating depth, which depended on the clues at the disposal of either eye alone. In stereoscopic vision, each eye had to form a good image, and that depended, principally, on the optical excellence of the iris. It seemed to be considered that for binocular vision all that was required was for both eyes to function, instead of only one. But there was only one visual field in consciousness, tho there were two ocular fields; and both ocular and conscious fields could not function with regard to the same spot at the same time. It was seldom that both eyes acted simultaneously: that was sometimes due to asymmetric astigmatism. It was important to try to find out how the ocular movements tested the balance of muscles. The eyes took up the right position for clear seeing if given plenty of time, but it did not necessarily follow they would do so when speed was essential. A test embracing the following of a moving field was therefore necessary.

Results of Ocular Examinations.

Mr. A. R. Brailey tabulated his results in the ocular examination of about four thousand candidates for the air service. The visual standard was, at first, very high, but later it was somewhat relaxed, and the fitting of lenses to the flying masks was permitted, and they proved quite satisfactory. Some officers asked for a difference in the shape, and others requested tinted glasses on account of glare. The lowest vision permitted was 6/18 with the better eye, 6/24 with the worse, corrected by glasses to 6/6 and 6/9 respectively. Binocular vision and a good sense of perspective were not always found to go together.

No rejections were made on account of faults of muscle balance, apart from actual squint. Flying failures were not found to be more numerous among the wearers of glasses than among others. Perception of the parallactic movement of objects he regarded as the all-important factor, but this he had found it difficult to assess by any test. When making a landing at a high speed, it was difficult to see the details of objects, and in that operation he did not think stereoscopic vision could be of great assistance. Little could be done in the way of correction of muscle defects by any form of training, however continuously carried out. Before candidates were accepted, details of their heterophoria should be available, both before and after treatment. For this service, a more important matter than acuity of vision in itself was the precision and rapidity of coordination between eye and brain: it was useless for a man to see perfectly unless he could accurately interpret, and act quickly in accordance with his perception. Flyers could not be selected by medical examination alone, any more than an efficient cricket team could be so selected from among the boys in a school: in flying, pluck, resource and response to stimuli were more important than medical perfection, especially in war time. Still, medical examination was important in regard to stress and fatigue, especially at high altitudes. Standards of light and color sensibility should be set up, so that parents could know, years beforehand, whether their sons were likely to attain to them. One very successful flying man in the service had 5 D. of myopia in each eye, and (probably as a result of wearing glasses) he had but indifferent binocular vision. A too stringent standard would exclude many otherwise desirable men.

Discussion: Major Clements said 26% of the men who came under his observation had glasses ordered, and they were turned down on account of bad landings. He described in detail the tests he employed and the results obtained. Of 294 men, 60% who were rejected on account of having made

bad landings had been in clerical or other close occupations. He had much of interest to say as to actual flying. The way in which the aviator knew whether he was flying level demonstrated the importance of good peripheral perception. The good flier looked at his horizon and used the nose of the machine as a protractor for measuring the flying angle.

Professor J. H. Parsons spoke of the need of research in this matter, of which the work done by Professor Spearman was a good example. This was the more needed on account of the already large amount of literature on the subject, too large a proportion of which was merely speculative. One of these important questions was that of heterophoria, and researches on the subjects coming within the scope of the present discussion should be against controls, as was the case in any well-conducted scientific inquiry.

Mr. Ernest Clarke spoke of the importance of testing under homatropin in every case, in order to exclude latent hypermetropia. Nearly all the men he had examined because they had crashed had hyperopic astigmatism, but they had been passed as what was termed "practically normal."

Col. Flack referred to the large range of capacity in candidates for the Service, and said that two very important questions had to be asked in this connection: (1) Was he likely to acquire the art of flying? (2) Was he likely to be able to stand the wear and tear of flying? He emphasized the point that a man with good arm and leg movement and coördination might fly successfully, even tho he might not have perfect vision. In regard to the second point, if a man's vision could be easily deteriorated by fatigue, that was a man one had to watch. But men's eyes could be greatly improved by rest and training. He thought a military pilot should have visual tests at varying altitudes for a period of at least one hour: An ophthalmic specialist should be there to test the vision. Even then much would remain to be settled. He thanked Professor Parsons for his suggestion as to research on this subject.

THE BOWMAN LECTURE.

Plastic Operations on the Orbital Region.

Professor Morax delivered the Bowman Lecture, taking as his subject "Plastic Operations on the Orbital Region, Including Reflection of the Orbital Cavity, Eyebrows and Eyelids." The author opened with a felicitous acknowledgment in the name of France of the high honor conferred on him, and thru him, on French ophthalmology, by asking him to deliver this lecture.

He said the prime motive for wishing to restore the appearance of the face when functional disability was not present was the avoidance of the unsettling curiosity manifested by the people met in the street, with which must be coupled the fear that his obvious defect would cause a lessening of affection on the part of those he held in esteem.

There should be avoidance of the use of tissues in the formation of a flap in the regions of motor nerves, and the utmost degree of asepsis must be insisted on. He found the skin surface was sufficiently sterilized by sterilized soap and tincture of iodin; any organisms remaining on them were generally saprophytic. Hairy flaps sometimes harbored saprophytic organisms, and these might afterwards cause little foci of suppurative folliculitis. It was necessary to devise a method of securing more perfect sterilization of hairy flaps.

When the conjunctival mucous membrane was alone at stake, one usually succeeded with physiologic salt solutions, with instillations of zinc sulphat or silver nitrat. It was easier for the lacrimal mucous membrane to be a source of infection. Some failures in this region had been due to operations having been done when there was latent dacryostitis, and in such cases the extirpation of the lacrimal sac and its diverticula would alone be efficacious, the lacrimal canaliculi being excised.

With regard to repairs of injuries to the *brows,* by burning or the explosion of powder, when only one brow has been involved, it was easy to detach its breadth, leaving a nasal pedicle, then fixing the isolated flap in an incision made symmetrically on a level with the upper margin of the orbit. When both eyebrows are destroyed, there must be recourse to nonpedicled hairy flaps, and these were less certain in results. He used for these cases flaps from the occipital region, fixing them in position by several mattress sutures. One disadvantage was that the hair on the new flap grew rapidly, and one of his cases had to have his eyebrows cut when he went to the barber.

With regard to repairs to the *eyelids,* an extensive cutaneous destruction on a level with the lids was followed by an obvious modification of the palpebral fissure, and the mutilation would be even greater when it involved skin and subjacent tissues, muscle, etc. The first act in such cases must be to bring together the margins of the two lids, after having freshened the mucous margins in the usual way. In most cases, the union of the lids must be maintained for two or three months. Professor Morax entered into the technic in detail.

He proceeded to speak of repairs to the *orbital cavity.* When the wound received involved total or partial destruction of the eyeball and its mucous membrane, there was a shrinking scar of the orbit, and more or less complete adherence of the lid tissue to the orbital tissue, and these symblephara prevented the wearing of an artificial eye. Sometimes enucleation had been done by a surgeon who did not appreciate the importance of conserving every bit of mucous membrane. One must wait until the process of scar formation had been consolidated and there were no more signs of infection, before attempting to graft. Whenever possible, one had recourse to cutaneous pedicle flaps taken from the neighborhood. He described various types of cases, and the procedures adopted.

With regard to complete *symblepharon,* if all the mucous membrane were destroyed, the method described would have to be modified. He had found it best to openly expose the parts to be grafted, and keep them open until the graft was in good condition. In some cases it might be necessary to combine the dermo-epidermic grafting method with the pedicled flap one in total symblepharon. Professor Morax concluded by describing his methods of securing a mobile support for an artificial eye.

Eyesight and Education.

On Friday morning, at the Royal Society of Medicine, an interesting discussion took place on the subject of "Eyesight in Connection with Education."

Dr. James Kerr said that at the present time any examination of the relations between vision and education rested much on the testing for acuity at school, while such matters as fatigue, functional troubles, the ocular results of various kinds of work, and the risks of visual deterioration were scarcely noted by those having the oversight of education. The use of the Ives' grating and testing each eye separately did not yield fair results; the second-tested eye usually gave the worst record, and he now abandoned the method. He much preferred the copying of test types by children using both eyes, as this gave practically all the results required, and there was no waste of time. These results also provided a good basis for mass investigations.

The tables in the earlier Board of Education Reports showed a great variation according to the districts concerned: e. g., 19.5 per cent with bad vision in Newcastle to 4.4 per cent at Ashton-under-Lyne; 11.3 per cent Lancashire, 4.8 per cent Gloucestershire. By careful testing of very young children with test types, Dr. Margaret Hogarth got 86 per cent normal vision in 800 infants, and only 3.2 per cent cases of bad vision. She took every precaution to keep the attention fixed, and introduced a number of requirements.

The local variations involved na-

tional problems, and were due, no doubt, largely to preventable causes, but there had not been any investigation on the question. He considered they were closely related to the general surroundings and were closely connected with the general health. The results in eye testing were largely influenced by the condition of the general cerebral cortex. Fatigue was important in academic work, and ocular fatigue, tho masked by great accommodative range in the young, was a contributor to nerve fatigue.

With regard to myopia, four-fifths of the children passed through all the strains and troubles of school life ocularly unharmed, but the majority who suffered from it became myopic. The increase of myopia year by year of age was not correlated to education, but to age. In a large number of cases Inglis Pollock showed that up to the 14th year 7 per cent to 8 per cent were myopic, but after that age it jumped to 15 per cent to 19 per cent, and remained above that figure. About puberty there was a real increase in the myopia present, also during the convalescence following acute illness.

Sweden, by adopting classical education and Gothic print, had greatly increased the proportion of good vision in the country. He proceeded to emphasize the great importance in this connection of general nutrition. There should be careful measures to avoid glare and strong light contrasts, and children should be spared all unnecessary fatigue. He indicated the lines along which he thought further investigation should be carried.

Discussion—Mr. N. Bishop Harman dealt with the clinical aspect of the subject, and he left out of account children who had attained to some stability of tissue and whose vision was good according to accepted standards. The remainder of the school population included (1) the immature, (2) the defective, (3) the blind.

With regard to class (1) the instability of accommodation and of binocular vision in early years was notorious, and this instability must extend to other functions. Owing to the intimate relation of brain and eye, the effect of any form of close work on the child was serious. To the child, even the recognition of figures and letters was a mental feat, and he believed the eyes felt fatigued according to the degree of mental exertion. Adults had only to remember the ease with which they could skim over a novel for hours, yet felt fatigued by a comparatively short study of a scientific treatise. Yet the daily routine of the school child was comparable to the latter.

When one read of the average work required of the average infant, one was led to inquire what was the average infant, but there was, as yet, no answer. No steps were taken to ascertain what the eyes of any particular infant were like, nor whether its defects would render the child incapable of bearing up against the strain put upon them. Between the fourth and seventh years the infant went thru a training at school without any medical eyesight examination. The refraction could always be measured. He had examined the refraction of all the infants in a high-grade school in the West of London. The eyes of each child were anointed with a fresh preparation of homatropin and cocain in castor oil (2% of each), then the child was allowed to sleep for an hour. After the examination the eyes were anointed with a minute smear of 1 per cent eserin in oil, to effect closure of the pupils as quickly as possible.

In this way 368 children, of ages 4 to 7, were examined. Only 8 wore glasses. Only 8 had emmetropic eyes, but there were 232 hyperopes, viz.: 130 under 1 D., 73 under 2 D., while those with not more than 3 D. were 29. There were 38 who had more than 2 D. astigmatism. Only very few had myopia of any degree, tho one child had 18 D., 7 had scarred eyes, 23 had anisometropia of over 1 D., while 8 had squint.

The summary of his conclusions was that one in every three was not fit to do ordinary school work under ordinary conditions, results which were striking and unexpected. He strongly condemned the practice of submitting young infants to school

work without a preliminary examination of their eyes. There should be a definite grading of the little ones at these early ages. Indeed, the subject was sufficiently serious to warrant its examination by a committee of this society. He concluded by a description of special methods, such as those seen by members at their visit that day to the schools at Camden Town and Hempstead Road.

The subject was discussed by Mr. Harrison Butler, Mr. Ernest Clarke, Mr. Percival Hay, Mr. A. L. Whitehead, Mr. Inglis Pollock, Mr. Evans, Mr. C. W. Thompson, and the openers replied.

On Friday evening a series of papers were read and discussed.

Angioma of the Choroid.

Mr. Treacher Collins and Mr. Leslie Paton reported a case. The patient, a boy, first came under Mr. Paton's care in 1917, when he was 14 years of age. There was a large nevus on the left cheek and outer side of left orbit. There was detachment of retina outwards and downwards. The tension of the eye was then normal. Puncture of the sclera was made with the galvanocautery, but the vision did not improve. A year later, an acute attack of glaucoma occurred, and the eye was removed. There was found to be a lens-shaped mass in the choroid, measuring 9 mm. in length, 5 mm in breadth, extending from the upper margin of the optic disc to a little behind the equator. There were the typical appearances of cavernous angioma. In the partitions between the vascular spaces on its inner surface were well developed lamellae of bone.

Presbyopia.

Mr. Ernest Clarke read a paper on presbyopia, a subject which, in the author's opinion, had been very inefficiently treated in the past in the various text books. Presbyopia synchronised with important body changes. The "squeezability" of the lens decreased with age; and in the normal emmetrope, at 48 years of age, it had decreased to such an extent that the person was conscious of requiring aid for near work. This was not a disease, but a physiologic change, which affected all eyes alike. He considered that true presbyopia was entirely dependent on the lens, not due to any weakness of ciliary muscle, except in advanced age.

Presbyopia was felt most at the time when eye strain was most liable to occur, and Leonard Williams and others had shown the dangers of hyperthyroidism, especially in connection with intestinal poisoning, for when the thyroid gland was deficient, the gate was opened for the poisoning of the system by toxins. He advocated the wearing of bifocal glasses. A mistake commonly made in these was to give a too strong reading addition to them.

Evulsion of the Optic Nerve.

Col. Lister and Capt. M. L. Hine contributed a paper on the condition of evulsion of the optic nerve. The authors had been able to find records of only 22 cases, and only 4 with a pathologic report, yet during the war this condition of the optic disc had become familiar. It was recognized either by a hole at the optic disc, which might occupy the whole or a part of the scleral ring, or the disc might be filled apparently with white. In both cases the retinal vessels had either completely or partially disappeared. The tearing of the tissue resulted in gross hemorrhage at the back of the eye, so as to obscure the field for the ophthalmoscopic examination. When, as occasionally happened, little or no hemorrhage took place into the vitreous, the ophthalmoscopic picture was one of the most striking possible: a fundus oculi without vessels, an optic disc replaced by an apparently bottomless glaucomatous pit set in a background in which there were dramatic concussion changes. The paper gave a minute description of the changes found, and was supplemented by a number of colored pictures, shown by means of the epidiascope.

Bilateral Choroidoretinitis.

Mr. E. Henderson read brief notes on a rare form of bilateral choroidoretinitis in a young child. The child, aged 6 years, was brought on account of occasional convergent strabismus of the left eye. After wearing correcting glasses and having the defective eye trained, the strabismus disappeared.

Two and a half years later, the sight having deteriorated, there was found in the right eye a brilliant white exudation to the macular side of the disc, in the center of which was a circular, partly pigmented patch. Some months later the left eye suddenly failed. A similar symmetric patch was found in the fundus, but accompanied by widespread exudation, and surrounded by some hemorrhage.

No source of infection could be found, and the Wassermann and tuberculin tests were negative. The scattered exudation gradually disappeared, and the appearance at present closely resembled that of the fundus of the other eye. He regarded the condition as due to some unexplained choroidal vascular lesion.

The following papers were also read:

Mr. Arnold Lawson: A New Method of Applying *Radium in Diseases of the Eye*, who described the rationale in collaboration with Mr. Sidney Russ. (2) Flavine in Ophthalmic Surgery.

Saturday morning was devoted to a *clinical meeting* at the Central London Ophthalmic Hospital, when many cases of interest were exhibited and discussed.

During the Congress, members visited the Day School for the Blind, Brecknock Road, Camden Town, the Myopia School, Exmouth, Street, N. W., and the Wellcome Museum, Wigmore Street. A dinner was held at the Welbeck Palace Hotel, and a museum of exhibits and specimens was established, under the care of R. R. James. On Saturday afternoon many members gladly participated in a golf match at Northwood.

ROYAL SOCIETY OF MEDICINE.

Sections of Ophthalmology and Laryngology.

These Sections held a combined meeting on Wednesday, April 2, Mr. W. T. Holmes Spicer occupying the chair. The subject of discussion was:

Injuries and Inflammatory Diseases Affecting the Orbit and Accessory Sinuses.

The Chairman expressed the hope that great good would come from the present meeting, which arose from the desire of ophthalmic surgeons to know a great deal more about the dangers which beset the precious optic nerve in its course from the eye to the brain. He remembered the time when there was but little expert knowledge concerning the ethmoid and frontal sinuses and when the departments of ophthalmology and laryngology at large hospitals were in charge of physicians, and the outlook upon them was purely medical. It was very important that the ophthalmologist should know when to call in an expert to deal with defective sinuses.

Mr. L. V. Cargill opened the discussion. It was, he said, surprising to find that cases of optic complications from sinus trouble were so few, because of the thinness of the partition dividing sinus from orbit. Ophthalmic complications might present themselves as functional disturbances, or as toxic effects. There might be contraction of the peripheral field, central scotoma, papilledema, papillitis, uveitis, episcleritis, subretinal effusion, retinal detachments, and so on. Nasal sinuitis was a chief cause of orbital inflammation. There was a small group of cases comprising retrobulbar conditions, and a larger one consisting of subperiosteal inflammations caused by extension from the nasal sinus. In ethmoidal cases, an acute specific fever seemed to be the usual primary cause. In young children, acute cases often responded to fomentation and good nursing. He asked whether the staff of ophthalmic hospitals should not include a rhinologist. If, in suspected

sinuitis, expectant treatment was not succeeding, an exploratory incision should be made without delay. In this war, the proportion of injuries inflicted by shell fire compared with those by rifle bullets was higher than in the South African war, and the sinuses had suffered in a correspondingly greater degree. Practically every case in which the wound was purely orbital had made a good recovery. The general results had been definitely aided by antitetanic serum, stereoscopic radiography, the telephone probe, and the electromagnet. No attempt had been made to remove deeply situated foreign bodies unless they were causing definite trouble. The essence of sinus treatment was efficient drainage and irrigation. He described and illustrated a variety of cases.

Mr. G. Seccombe Hett remarked on the benefit of such coöperation among experts, not only in regard to the more efficient treatment of war injuries, but also cases of injury met with in industrial practice and in disease. His experience during the last three years had been with cases from the war after their arrival in England. The best results followed free drainage and as little movement of bony and soft tissues as possible. Mucous membrane was stitched to skin, and was not taken away. In a number of cases he had been able to reconstitute an eye socket because the conjunctival mucous membrane had been retained. He showed an instructive selection of slides illustrating treatment in a variety of conditions.

Mr. A. W. Ormond based his contribution on the cases which had come under his care at the Second London General Hospital during the last four years, and in particular on 100 cases. He could not say that serious damage to orbit or sinuses had resulted in any subtle change in vision; the results were those of the original injury, or of inflammatory change set up by it. In some patients there was optic neuritis in the uninjured eye. Pain arising in consequence of inflammation of the sinuses was sometimes referred by the patient to his eye. In two cases, blind eyes had been removed on account of severe pain supposed to originate in them, but it was found to have arisen in the nasal condition. Sometimes a deep wound was found to have affected four sinuses.

Mr. E. D. D. Davis spoke of his experiences in this connection at casualty clearing stations. He had been struck with the frequent occurrence of a fissure-fracture of the roof of the orbit when making postmortem examinations in cases of bullet wounds of any part of the skull. Fracture of the anterior fossa was accompanied by diffuse intradural hemorrhage, and these cases usually succumbed in twenty-four hours. Even if this period was survived, death took place in from three to six days, from basal meningitis, due to infection of the wound cavity. In cases of sinus injury, he regarded early suture as very important. He asked for opinions as to the wisdom of draining severe orbital cellulitis through the nose. Suppuration of the antrum, of nasal origin, was nearly always accompanied by suppuration of other sinuses also, but in cases where the suppuration in the antrum was due to the condition of the teeth, the antrum remained the only cavity involved, and in such cases no retrobulbar neuritis had been recorded.

Mr. H. D. Gillies expressed his objection to the early suture advocated by Mr. E. D. Davis. In the honeycomb presented by the sinuses one could not excise the whole wound, and early suture meant giving a good deal of trouble in the later stages of (restorative) treatment. Excision of the wound in a fleshy part was quite justifiable, but it was not possible in the sinus region. In the next Bolshevik war the best practice would be found to be to keep entrance and exit wounds open as much as possible, so as to permit of efficient drainage until no question of suppuration remained. Very great benefit had resulted in the treatment of war injuries by the coöperation of the dental and the plastic surgeon, and he hoped much from the combination of the efforts of rhinologists and ophthal-

mic surgeons, of which this meeting was an earnest.

Mr. D. Leighton Davies spoke of the effects of nasal sinus affections on the fields of vision and on the ocular muscles. Some cases of heterophoria were secondary to sinus affections. The fields should always be studied, because patients did not make voluntary complaint in this respect. He had never met with a case of chronic nasal suppuration which did not show some changes in the visual fields. There might be scotoma, or an enlargement of the blind spot. When sinus disease had been operated upon, the blind spot enlargement subsided, only to again enlarge if the nasal trouble returned. Even when the field of vision was reduced to 10°, he did not find the patients complained of difficulty in orientation. If the sinus trouble had been long-lasting, its cure did not always result in complete restoration of visual fields. In discussing the etiology, he said no one theory yet advanced would account for all the cases. The discharge from the involved sinuses, being swallowed, set up a toxemia, which so spread to the eye. If that were true, one might expect to find contraction of visual fields in association with suppuration in other parts of the body, but he had not yet found that in sufficient numbers to warrant the drawing of conclusions. He had, however, found contraction of fields in cases of chronic suppurative osteomyelitis, chronic otorrhea, and leucorrhea with endometritis.

The debate on this subject was resumed on April 10, the chair being occupied by Dr. James Donelan, the President of the Section of Laryngology.

Mr. W. M. Mollison, in reopening, said most of the cases of the kind under discussion which he had seen were those which had been under the care of Mr. Ormond on account of damage to the eyes, and he did not see them until some months after the receipt of the injury. He had been impressed with the amount of time and trouble and suffering on the part of the patients which might have been saved if an ophthalmologist and a rhinologist had attended the cases from the commencement. This was especially so in the cases in which drainage into the nose might have been effected before any attempt was made to repair lids or sockets. When the latter had been done there was often a persistent pus discharge. He divided the cases he had seen into clean thru-and-thru bullet wounds, and secondly all other kinds. The usual result in the former was adhesion between outer wall and septum. Infection of sinuses was generally a sequel of the obstruction. All the cases he saw—at St. Dunstan's—were blind, some completely so. In one case, in restoring the nasal airway, he opened an adhesion between the septum and ethmoid, and infection of the meninges took place. The result appeared to be very good, but three weeks afterwards the officer developed meningitis and he died in three days. In some there was parosmia, due to damage of the olfactory nerve. Among the men at St. Dunstan's he found the sinus most frequently affected was the frontal; the proportion was 13 frontal, 2 antral. In some cases the deep wall of the sinus had been fractured and dura mater exposed. One man was wounded by a shell in May, 1917; shrapnel entered the right side by the canthus, and he had a sinus round the right inner angle of the orbit. At the operation a very extensive ethmoiditis was found, and there was a large piece of khaki clothing in the ethmoid, which had been there seven months. He had not yet discovered a case of sinus suppuration in connection with retrobulbar neuritis, tho he explored in a routine way with a Killian's speculum. He had seen only one case of orbital cellulitis which could be called idiopathic. It was that of a girl who was admitted into Guy's Hospital desperately ill. He could find nothing wrong with the sinuses. She died in two days of most extensive pyemia, and no primary source could be discovered. In 99 per cent of these cases he thought the sinus at fault was the frontal.

Mr. J. F. O'Malley said he had notes of about 60 cases of trouble in

nasal and accessory sinuses in which there were also eye lesions and injuries of the lacrimal apparatus. In the case of wounds of the ethmoid he had found that where there was previous obstruction sepsis was invariably present, and free incision and thoro drainage was needed. But he had been struck by the fact that in a large percentage of his ethmoidal cases there was so little spesis that extensive treatment was not called for beyond the removal of adhesions. In the case of gunshot wounds, there was great facility in healing once a good airway had been reestablished; this in contrast with ordinary ethmoid involvement secondary to nasal inflammation. Much the same could be said of antral lesions. Out of 50 thru-and-thru wounds of the antra he had only to operate on 11 for sepsis; in 11 others he operated for the removal of foreign bodies. He had 18 cases of eye involvement; in 10 the eye was lost, in 8 there were injuries to it of varying degree. Where the injury to the eye was not direct, it seemed to have been caused by the missile striking the malar bone, the shock of impact being communicated to the bony wall of the orbit. In some cases where epiphora resulted, this did not give much trouble in the ordinary way, but when playing games in a high wind, or motoring, the overflow of the tears was a nuisance. He thought the cause was hypertrophy of the inferior turbinate due to exposure to the winds, and as a result of its engorgement pressure was exerted on the tear duct. Removal of a portion of the soft tissue of the inferior turbinate seemed to cure this climatic cause of overflow.

Mr. G. H. Pooley said orbital cellulitis was often due to extension of inflammatory trouble in the superior ethmoidal sinus or from the lacrimal apparatus. In children, orbital cellulitis was often due to osteomyelitis in the frontal or ethmoidal region, and frequently these cases died. The best treatment was free incision, and the generous use of the sharp spoon. Defective vision due to nasal conditions he thought was attributable to pressure on the optic nerve, or to toxic influence of the retinal cells.

Mr. W. Stuart-Low spoke of cases in which edema spread to the canthus from inflammation of the frontal sinus. In some of the cases sent for operation, in which the middle turbinal was swollen and was blocking the passage, he avoided operation by using cocain and adrenalin, following that, after an interval, by fomentation. He did not operate until he had tried some such measures. Relieving the tension in a sinus, which might be due simply to serous fluid, was of great benefit. If these means failed, he received the patient into the hospital and incised freely under the eyes. He refrained from washing out the frontal sinus, for fear of driving infecting material into other sinuses. Removal of two-thirds of the middle turbinal often succeeded. He also made a practice of using a cage over wounds of sinuses and ears, to obviate pressure from outside, and he believed that had much to do with preventing or reducing subsequent deformity. Some of his lacrimal cases he failed to cure, and then he generally found some small foreign body was the cause of failure. He employed washing out in the case of the antrum, for its partition, tho thin, was complete. When a portion of shrapnel or casting was deeply embedded, he did not attempt removal unless it was giving the patient trouble.

Mr. Herbert Tilley showed photographs to demonstrate that ethmoidal cells and frontal sinus were developed quite early, even at three years of age. He also exhibited skiagrams of cases. He said that sometimes frontal sinus inflammation caused contralateral retrobulbar neuritis. Subjects of sinus suppuration seldom complained of eye symptoms, and even when asked directly about them did not admit such. In cases which had been referred to him by ophthalmologic colleagues, having gone to them because of retrobulbar neuritis, he seldom found sinuses involved, which he attributed to the fact that the originating nasal trouble had cleared up in the meantime. The rapidity with which eye

symptoms cleared up when nasal trouble was treated seemed to show that the cause was pressure of fluid rather than actual sepsis. Radical measures should never be undertaken during acute intranasal infection; it might mean disaster to the eye, or even to life. At this stage the surgeon should be satisfied with providing free drainage. He had seen iritis, cyclitis, and some internal affections of the eye quite cured by intranasal operations. He had never seen a case of orbital cellulitis in which sinus suppuration was not present.

Mr. Lawson Whale brought out, by means of an epidiascope demonstration of selected skiagrams from his war experiences in France and England, a number of points of practical importance in diagnosis and treatment.

After a few closing remarks by the Chairman, the four openers briefly replied.

H. Dickinson.

COLORADO OPHTHALMOLOGICAL SOCIETY.

March 1, 1919.

Dr. C. A. Ringle, Presiding.

Glaucoma Simplex.

H. R. Stilwill and Melville Black, Denver, presented a man of fifty-three years who had a simple glaucoma in both eyes, and on whose left eye corneoscleral trephining had been done. The patient had come on October 3, 1917, on account of moderate blurring of vision. The pupils were rather large and sluggish, the anterior chambers shallow, and the tension of either eye 55 mm. with the Schiötz tonometer. There was cupping of both disks, more marked in the right eye. The vision at this time was R. 4/4, L. 4/5. Under eserin the vision improved and remained normal until October, 1918, when it dropped to R. 4/5, L. 4/6. On January 17, 1919, Dr. Black performed sclerocorneal trephining on the left eye, combined with iridectomy. The vision before operation was R. 4/7, L. 4/20. The vision recorded on February 18, 1919, was R. 4/7 part, L. 2/60. The anterior chamber had remained completely empty for about a month after the trephining was done, and then gradually refilled. The tension then gradually came up, but was still subnormal (17 mm.). The reduction in vision had apparently continued speedily after the operation. The glaucoma cup, which had never been marked, was about the same. Dr. Black remarked that it was a serious question what was best to do for the other eye, since iridectomy had not proved very successful in simple glaucomas. The patient was approaching the point where he could not do his bookkeeping satisfactorily. The vision in the good eye was now 20/40 part, and eserin did not seem to be holding it, but the eye was changing for the worse fairly rapidly. The tension remained about 40 mm. all the time. The visual field of this eye showed comparatively little contraction.

Discussion. J. A. McCaw, Denver, mentioned a recent report in the literature, of a case in which atropin was used in the presence of subnormal tension and brought up the vision.

Dr. Black said that the operated eye had been kept under atropin until three or four weeks ago, but that the atropin had not improved the tension.

Edward Jackson, Denver, pointed out that the field which had been shown for the operated eye had been taken on the second of December shortly before the operation, and indicated that at this time the boundary of the field was cutting pretty close to the fixation point. The boundary was probably closer to the fixation point than the chart would show, as such patients do not fix very accurately. It often happens that operations on such eyes are followed by a further limitation of the field which carries it beyond the fixation point. In one case seen in consultation some years ago, the patient could read with the eye before operation, but after operation the eye was entirely useless. The operation is not to be blamed on that account, but this is one of the risks which have to be taken in operating on such an eye. The patient should probably be advised

to have an operation done on the second eye, and the best operation might be a Lagrange with a rather large iridectomy.

E. R. Neeper, Colorado Springs, was disposed to try the effect of the high frequency current, and would do a simple iridectomy on the second eye.

H. M. Thompson, Pueblo, emphasized the possibility of a toxic basis for glaucoma, and recalled a case which he had shown two years earlier in which removal of streptococcic tonsils had apparently checked the course of glaucoma.

C. E. Walker Denver, thought that it was seldom found that the points which Dr. Thompson had mentioned had anything to do with this form of glaucoma. A decrease of vision after operation was fairly frequent. As to the second eye, the reduction of vision under the best treatment made iridectomy the thing. In association with the iridectomy it would be advisable to use the procedure of Priestley Smith, scleral puncture with a Lang knife (slightly smaller than the Graefe), then through an incision one-fifth the corneal circumference to make a large iris excision, cutting first to one side and then to the other, and pulling on the iris until it tore.

Dr. Stilwill stated that the patient's physical condition had been gone over thoroly, but his teeth were perfect, and he had never had any illness apart from the eyes.

Dr. Black did not feel disposed to do posterior scleral puncture except as a last resort in blind and inflamed eyes. He was afraid of cutting a large choroidal vessel.

Dr. Walker said he had never cut such a vessel in doing this operation.

Keratoconus.

H. R. Stilwill, Denver, presented a man of thirty-four years the vision of whose eyes had been failing for the past six months. The uncorrected vision of the right eye was 1/60, of the left eye counting fingers at two feet. With R. —15.50 sphere combined with —3.50 cylinder axis 145 degrees the vision was 4/60, and with L. —15.50 sphere combined with —3.50 cylinder axis 60 degrees the vision was 4/15. There was marked conical cornea in each eye. The patient had been given a weak solution of pilocarpin. No disturbance of the corneal tissue except the conicity could be made out. The periphery of the cornea and of the anterior chamber could be seen thru the conical cornea better than with most eyes.

Melville Black, Denver, thought that we were disposed to overestimate the amount of astigmatism in these cases. He had found it pay to start in arbitrarily with an estimated plus cylinder and work behind it with a minus sphere, afterwards adjusting the axis of the cylinder.

J. A. McCaw, Denver, had found it advantageous to test such cases under pilocarpin.

Edward Jackson, Denver, advised treating these eyes with pilocarpin over long periods.

Vernal Conjunctivitis.

E. R. Neeper, Colorado Springs, presented a young man of eighteen years both of whose upper eyelids presented on the tarsal surface the typical cobblestone formations of vernal conjunctivitis. There had been the usual symptoms of redness, itching, swelling of the lids, and watering of the eyes, with improvement in cool weather. A sister had the same symptoms with a good deal of pain. The enlarged papillae inside the upper lids were rather distinctly pedunculated. The cornea of the right eye presented a superficial ulcer a little above the center. X-Ray and radium treatment had been advised, but not been used to date.

Discussion. Edward Jackson, Denver, referred to a case which he had reported some years previously to the Colorado Ophthalmological Congress. This patient had recently returned. He had got into the naval training school, but was finally turned down on account of his eyes. He had recently been put under radium, with beneficial results.

Shrunken Eyeball Following Pneumonia.

C. O. Eigler, Denver, presented a girl aged four and a half years who was said to have had pneumonia with convulsions at two and a half years, and to have subsequently developed severe pain in the head over the left eye, lasting eight days. Upon recovery from this condition the eye turned in and was blind. The eyeball was small, sunken in the socket and soft. It was still sensitive to light in the mornings.

Discussion. Melville Black, Denver, believed that the original condition had been a choroidal disturbance metastatic from pneumonia. It was probably better to leave the eye in a growing child, postponing the question of removal for later consideration.

Edward Jackson, Denver, suggested that if there was no irritation from the eye, it was just as well to leave it alone. It was, however, the sort of eye which might produce sympathetic irritation; and this, while not likely to destroy the other eye, might interfere with the use of the good eye. As regards the development of the orbit, Dr. Jackson had seen a girl of 16 whose eye was removed some fourteen years previously, yet it was impossible to discover any difference in the development of the two orbits.

C. E. Walker, Denver, emphasized the fact that in most of these old cases of choroiditis there was later on a bony formation which acted as an irritant, so that he believed it would be better to remove the eye before such a condition developed.

J. A. McCaw, Denver, asked how an opticociliary resection would serve in this case.

Dr. Black replied that enucleation would probably be better if the eye were keeping up interference with the use of the other eye.

Strabismus Under Voluntary Control.

W. C. Bane, Denver, presented a man of twenty-one years who had had a diverging strabismus of the left eye since childhood, without other symptoms. The divergence was probably sixty or more centrads, but was made difficult to measure by the ability which the patient had to draw the left eye in so that it was in line with its fellow.

Discussion. C. E. Walker, Denver believed that in such a case the best operation would be an advancement, with in all probability a tenotomy at the same time.

E. R. Neeper, Colorado Springs, had never had much success with advancement, but got better results with resection.

Steel in Anterior Chamber.

E. E. McKeown, Denver, presented a man whose left eye had been struck by a small piece of steel while he was driving a pin into a wheel. The foreign body had become embedded near the center of the cornea, and the home physician had unsuccessfully attempted its removal. On examination by Dr. McKeown the cut in the cornea was found, but no foreign body. The steel had apparently been pushed into the anterior chamber, in the angle of which it was shown by the X-ray, altho invisible to the eye of the examiner. Was it possible to remove the peace of steel from this location, or should it be left in place?

Discussion. Melville Black, Denver, suggested the possibility of bringing the tip of the hand magnet into contact with the foreign body, but thought it might be well to wait a while and see what happened.

C. E. Walker, Denver, recommended the use of small tips for attachment to the giant magnet.

Edward Jackson, Denver. The value of the giant magnet is that it works at a longer distance. There is less power right at the tip of this giant magnet than there is an inch or so away. The small tips attached to it make it very much more more serviceable. A Dutch ophthalmologist has recently written a valuable paper on the withdrawal of foreign bodies from the anterior chamber. He uses a T-shaped incision, an incision parallel to the margin of the cornea, and an incision at right angles to it; and thus succeeds in getting out

foreign bodies which cannot otherwise be got at.

Sarcoma of the Ciliary Body.

H. M. Thompson, Pueblo, reported a case of mixed cell sarcoma of the ciliary body. The patient, a woman of forty-four years, first experienced visual disturbance in the right eye in November, 1915. There was a gradual development of pain in the eye and on the same side of the head. A little over three weeks later, after having failed to obtain relief from a nasal operation done by a traveling surgeon, she consulted Dr. Thompson. The eyeball was stony hard, the lens cataractous, and the general condition of the eye was that of absolute glaucoma. On opening the enucleated eyeball, a light gray mass, the thickness of a small pencil and slightly flattened, was found behind the iris, and taking origin from a definite point in the ciliary body. The other end of the cylindric mass was free in the vitreous. The ciliary body was not infiltrated by the sarcoma, nor had any other tissue of the eye seemed affected except by the changes incidental to the glaucoma. Dr. C. W. Maynard, pathologist, reported the tumor to be a mixed cell sarcoma practically free from pigment.

Calcareous Lens in Anterior Chamber.

Edward Jackson and Melville Black, Denver, exhibited a calcareous lens which had been removed from the anterior chamber, into which it had apparently migrated after remaining for a long time in the vitreous. The patient, a woman of fifty years, had apparently undergone two operations, at the first of which iridectomy was done on account of previous inflammation which had left the pupil adherent to the lens, and at the second of which (three years ago) the cataractous lens had been pushed back into the vitreous. The lens had come foreward in the anterior chamber three weeks ago, and had stayed there. The shrunken lens, yellowish white in color, was removed through a large corneal incision above. A more than the normal amount of aqueous humor escaped, the excess being regarded by Dr. Black as having come from the portion of the vitreous which had contained the dislocated lens. The eye then collapsed badly, but after waiting ten minutes it was possible to remove the cataract from the anterior chamber with a wire scoop. The wound healed readily and almost without reddening the eyeball. The extracted lens proved to be calcareous shell, six or seven millimeters in diameter.

Wm. H. Crisp, Secretary.

CHICAGO OPHTHALMOLOGICAL SOCIETY.

A regular meeting was hald March 17, 1919, with the President, Dr. William L. Noble, in the chair.

Gumma of the Iris.

Dr. N. C. Nelson exhibited a young man with a tumor of the iris which was diagnosed as a gumma. Patient had been placed under treatment with mercurial inunctions and the iodids, and the gumma had begun to disappear.

Dr. Noble asked how long it was since the iodids were begun, to which Dr. Nelson replied about two and a half weeks.

Xeroderma Pigmentosum.

Dr. Nelson also showed a patient stating that the case really did not be long to this department except that one could see the thickened condition of the lower lid and the ectropion, and in these cases the cornea generally became ulcerated. In other words, there was an ulcerative keratitis. The condition was known as xeroderma pigmentosum and generally began in the very young. It began from six months up to four or five years. The pigment very much resembled freckles which appeared on the exposed surfaces, such as the face, neck and extremities. The pigment became deeper, and a little later on there was a warty appearance as was seen in this case, and still later ulcers developed. The tendency was for this condition to take on the malignant epithelial type. The prognosis was generally fatal. The sun and wind

were the causative factors of this condition.

As far as treatment was concerned, there did not seem to be any outside of palliative treatment.

Up to 1870 there had not been many of these cases noted and reported, but between that time and 1910 there had been something less than 100 cases recorded in the medical literature of the United States.

Discussion: Dr. Alfred Murray stated that in Fuchs' clinic, where over 20,000 new cases were seen annually, only two of the type presenting the condition described by Dr. Nelson were seen by him during the year that he was there; showing the rarity of this very interesting pathologic condition. These two cases were in sisters.

Dr. Nelson stated that the body was free from pigmentation where it was not exposed to the wind or sun. There was pigment on the hand, but as one went above where the clothes protected the body this pigment did not manifest itself.

There were no more cases in the same family. Occasionally more than one case was known to develop in a family. One physician had reported seven such cases in one family of which there were thirteen members.

One characteristic of the disease was that if the epithelial growth began early, the termination was likely to be more rapid than when it began late.

Dr. Smith asked Dr. Nelson why he did not treat the case of xeroderma pigmentosa with the X-ray.

Dr. Nelson replied that the case was sent to a leading skin specialist in Chicago in the first place, and he asked the specialist why he did not use the X-ray treatment, and his answer was that the disease was not favorably affected by the X-ray.

Hemorrhage Into the Vitreous.

Dr. Carl O. Schneider reported the case of a man who, six weeks ago, had been hit in the eye with a pair of brass knuckles, which caused considerable hemorrhage into the vitreous.

Double Paralysis of the External Recti Muscles.

Dr. E. R. Crossley showed a case of double paralysis of the external recti muscles that had been operated on recently by Dr. Woodruff, who resorted to the transplantation of the external half of the superior and inferior recti muscles. The man was struck on the back of the head about six months ago, shortly after which this paralysis developed.

Dr. Von Der Heydt asked for further information regarding the case of double paralysis of the external recti.

Dr. Crossley stated that the object in showing the case was to refer to the transplantation of the superior and inferior recti muscles. This operation was described by Dr. Woodruff two years ago before the American Medical Association, at which time Dr. Woodruff reported two cases on which he had performed this operation. This was the fourth case. Advancements were done on both external recti before Dr. Woodruff had operated.

Dr. Noble asked whether there was any pull by either of the external recti.

Dr. Crossley replied that there was pull in both eyes. In the left eye there was a little deviation upwards, and Dr. Woodruff had attempted to correct that, but with what result he did not know.

Dr. Noble asked how long it was since the operations were done.

Dr. Crossley replied about a month as regards the right eye, and there was a week between operations. The first two cases were reported in the proceedings of the Ophthalmological Section of the American Medical Association for 1917, and in this paper Dr. Woodruff covered quite extensively the subject of transplantation of tendons elsewhere and in the eye. There was only a few such cases reported before that time.

Dr. Von Der Heydt said that two years ago he saw a case similar to the one shown by Dr. Crossley of paralysis of both abducens nerves in the same individual. It could not be justified anatomically at all. It should not be called a paralysis of both external

recti. The literature maintained that these cases were usually a convergence spasm, and that the origin of it was either some irritation in the brain, hysteria, or possibly multiple sclerosis.

Dr. Crossley stated that trauma was excluded in these three casas. He did not see how external trauma could paralyze both external recti, nor could he say anything about the origin of it any more than that the man was struck months ago and fell on the back of his head, and that was the beginning of his trouble. The man had gone through the operation of advancement of both external recti some time before, and had had no previous trouble.

Dr. Nelson said the man had had no previous trouble. He was on a drunk, got into a scrap, and came to the clinic the next morning with both external recti paralyzed. At present, after operation, he had considerable motion in the right eye, but in the left it was not quite so marked. The last operation on the left eye was only done March 14, 1919.

Enucleation of the Eyeball Under Local Anesthesia.

Dr. Austin A. Hayden read a paper on this subject in which he stated that local anesthesia, since Koller introduced cocain in 1884, had been the procedure par excellence in nearly the entire realm of ophthalmic surgery. Today general narcosis was not uniformly employed in eye operations except on the very young and extremely nervous patients; in septic conditions, where injections might carry infection to other tissues; in extensive plastics and in enucleations. In some of the last named the use of chloroform or ether might be so dangerous to the life of the patient as to be almost absolutely contraindicated. Local anesthesia then became a matter of necessity. A most satisfactory result in a case of this sort had prompted the presentation of his paper.

After detailing an interesting case in which he enucleated the eyeball under local anesthesia, he referred to the advantages or indications for local anesthesia in general: 1. Dangers and complications of general anesthesia are entirely eliminated. Among these are the immediate dangers, such as respiratory and cardiac failure, chloroform and ether poisoning and shock, as well as remote complications, such as postoperative and hypostatic pneumonia, myocarditis, and nephritis.

2. It is impossible to remove the wrong eye.

3. No preparation is needed, so that the operation can be done at once, and it is not necessary for the patient to be purged or starved.

4. No assistant is necessary.

5. The surgeon is relieved entirely of worry in regard to the patient's life.

The contraindications of local anesthesia are few: 1. Extreme youth or extreme nervousness on the part of the patient, probably also the latter on the part of the operator.

2. Purulent conjunctivitis and panophthalmitis, where theoretically a dissemination of the infection might result from injection of the anesthetic solution used.

3. Ruptures of the globe from panophthalmitis.

The author quoted extensively from the literature favoring enucleation under local anesthesia.

Discussion: Dr. Alfred N. Murray stated that Uhthoff in Breslau had done a great many enucleations under local anesthesia. After the muscles were released, he injected the cocain solution into the region of the ciliary nerves at the back of the eyeball through a long curved needle. The patients were able to talk to him during the operation and complained of no particular pain. The results were excellent. He did not think of giving a general anesthetic except to young children and nervous people, and ordinarily the patients came thru without any trouble whatever.

Dr. Thomas Faith stated that for a number of years Dr. Fisher and Dr. Hoffman had both done a number of enucleations under local anesthesia. Dr. Hoffman preceded the local anesthesia with H. M. C. He had personally done a few enucleations under

local anesthesia, but the technic described was one that he had not followed. In injecting the muscle attachments no attempt was made to penetrate the globe. He believed that the administration of the H. M. C. facilitated the work. He had done a number of enucleations with the aid of this combination under local anesthesia in patients who were so nervous that he was unable to do the work with local anesthesia alone, and yet they were patients to whom he did not wish to administer a general anesthetic. In his last case he resorted to the use of apothesin, a local anesthetic produced by Parke, Davis & Company, and said to be of no value except for injection into the tissues. It is of no value as a local anesthetic when applied to the mucous membrane. The result was satisfactory if the H. M. C. was given according to instructions. The first injection was usually given an hour before the operation and the second one was given half an hour before the patient was put on the operating table. Towards the close of the operation the effect seemed to be very satisfactory, and the patient experienced no pain whatever when the nerve was cut. Deep injections were made with the two per cent apothesin, the same as subconjunctival injections into the muscle sheath, and no cocain except four per cent solution was used and that was instilled at the beginning. One could use large quantities of apothesin; as much as two ounces had been given subcutaneously for extensive superficial operations and no deleterious effects ensued.

Dr. H. J. Smith asked why the essayist did not use novocain, which he thought was safer for the patient if he wanted to use any quantity. The injection should be made in the loose tissue of the orbit. Unless one placed the cocain solution very accurately he could hardly accomplish his object without using too much. With novocain one could infiltrate the entire orbit and cover the ground very well and at the same time keep within the bounds of safety.

He also asked Dr. Hayden why he injected cocain into the vitreous chamber. There might be a reason for this, but it was not apparent to him.

Dr. William A. Mann said he had operated on two cases and was pleased with the operation. He did not think it necessary to go through the eyeball to anesthetize the tissues back of the eyeball, as those same tissues could be reached by rotating the eyeball after the recti muscles had been cut. In the two cases on which he had operated the pain was not entirely relieved, although if he were to have the operation done on himself he would prefer local anesthesia to ether unless there was very marked sensitiveness of the ciliary nerves.

Dr. Hayden, in closing, stated in regard to the use of hyoscin, morphin and cactin that it properly came between local and general anesthesia, but he could readily see how it would be a distinct help for any local anesthetic procedure that might be attempted. Of course, the hyoscin was a powerful toxin and even in small quantities should be used very guardedly, and he did not know whether the use of those drugs together with the cocain that was employed was a good thing if a satisfactory degree of anesthesia could be obtained by the use of cocain alone.

As to the penetration of the globe, he simply wanted to try it. He figured it out this way: it was perhaps easier to penetrate the globe and reach the terminations of the ciliary nerve that lie around the optic nerve instead of going back of the ciliary ganglion along the path of the external rectus muscle. There was a difference in depth of about an inch. The ganglion was located nearly two inches back, whereas going straight through the globe the termination of the same nerves could be reached fully an inch further forward. It seemed to him that puncture and counterpuncture of the globe was attended by absolutely no risk, although he had only done this in one case. It was apparently quite easy to strike the sclera just to the temporal side of the optic nerve, and on the second injection to strike it just to the nasal side of the optic nerve by

rotating the needle about fifteen degrees.

Dr. Martin, from South Dakota, who happened to be in Chicago at the time, had witnessed the operation, and he felt that the severance of the optic nerve would be attended by great pain. So far as the speaker knew, the optic nerve itself was absolutely insensitive, but the small nerves which lie close to the optic nerve just before they perforate the sclera were sensitive. This was what was meant by saying that dividing the optic nerve might be attended by a considerable amount of pain. It was not the pain from the cutting of the optic nerve itself but the ciliary nerve branches in the vicinity. Lastly, if he was unfortunate enough to have to do many of these operations he would resort to local anesthesia.

As Dr. Murray had remarked, enucleations were done under local anesthesia as a routine procedure, in certain European clinics (notably in Paris). More of these operations could be done here in America, especially in selected cases, with great advantage to patient and operator as well.

Dr. Noble asked Dr. Hayden if he thought with a plus three tension he could have manipulated the eye without pain under cocain anesthesia, if he had not opened the sclera and reduced the tension?

Dr. Hayden, in replying, stated that he had the feeling the intraocular injections could not have been made without causing great pain unless the tension was first reduced.

In answer to Dr. Smith, he stated that there was no particular reason for the injection of the cocain inside the globe except this: The chances were it would be rather slowly absorbed into the circulation from the globe cavity, and that it was at least not dangerous if given in this location. In the second place, there might have been some chance of reaching the region behind the nerve through the return ciliary circulation.

Lenticular Lens for High Myopia.

Dr. Carl O. Schneider remarked that when prescribing concave lenses of about ten diopters or more, we were well aware of the excessive weight and thickness, and of the conspicuous rings or reflections of the edge that were present in concave lenses of the ordinary form.

To overcome these objections, the well-known lenticular lens, consisting of a plano or perfectly flat piece of glass with the concavity ground in the center, had long been in use. This form of lens gained only a slight reduction in weight and thickness, and it had the disadvantage of only a small concave area, and this area could be increased in size only at the expense of the objectionable added weight and thickness.

It occurerd to him sixteen years ago, while studying optics, and making diagrams of the course of a ray of light through various forms of lenses, that the combination of concavity in the center of a convex piece of glass would produce a lens suitable for the correction of a high degree of myopia, and which would contain a much smaller amount of glass, and at the same time admit of a larger concave area, than did the ordinary lenticular or any other form of concave lens then available.

Upon inquiry, he found that no lenses of this type had been made, and certainly none like it were in use before the time he applied for the patent which covered the subject of this paper.

He quoted from specifications on Patent No. 744,982 that was issued to him November 24, 1903, as follows: "The present invention consists in forming a concave lens by grinding a central concavity of the desired curvature in a main body portion of the required dimensions, and which body portion is of a double-convex, a plano-convex, or a compound-convex form. As so formed a concave lens for spectacles and like uses is produced containing a much less quantity of glass for a concave lens of a given focus and size than it had been possible to pro-

duce heretofore. The present invention also renders it possible to grind a concave lens with thin edges, and thus entirely eliminate the numerous objectionable and annoying reflections or rings which appear in a concave lens of the ordinary form. In addition to the foregoing, the present invention affords a lens of a neat and pleasing appearance, and its thinness at the

Figs. 1-6. Schneider's Lenticular Lens for High Myopia.

margin permits of a very ready, neat, and substantial attachment to the spectacle rim or to the straps of a rimless mounting."

With the aid of the toric lens surfacing machine, it was possible by applying this same principle to produce the concave surface in an oval form, and the Schneider oval lenticular lens was undoubtedly the most beautiful concave lens that it was possible to prescribe for a patient having a high myopia.

In the author's experience, myopes of ten diopters or over would gain sufficient advantage by reduction in weight and by improved appearance to warrant the use of some form of this lens; but it was particularly in cases requiring a correction of about —20.00 D. or more that the patient was considerably benefited and invariably delighted with this new form of lenticular lens.

In obtaining this patent, the object was merely to definitely establish the fact that he had made this slight contribution for the good of humanity. No restrictions had ever been imposed against the free use of these lenses. No fee or royalty had ever been charged or collected under this patent, and he was permitting all optical shops to make any of these lenticular lenses without any financial obligation to him whatever.

Discussion: Dr. Michael Goldenburg said he had been familiar with the Schneider lenticular lens, but did not know that a member of the society or resident of Chicago was the inventor of it. He had been using this lens for a number of years; it was a beautiful thing and gave much finer and clearer vision than any lens on the market.

Dr. Robert Von Der Heydt stated that owing to the present tendency toward larger lenses, the myope especially was very badly handicapped.

He had been using these lenses for years, and also used the toric lenticular lens in which the bevel edge was toric instead of plus sphere. It gave an oval instead of a round field, which made it a good looking lens. There was one optical company which produced a similar lens by beveling the edges by hand on the grindstone. He thought it would be a good idea to make these thick lenses out of flint glass having a higher index of refraction. In this way we should get a thinner lens diopter for diopter than with the usual crown glass.

While the subject of lenses was up for discussion, he would like to mention a very great and seemingly unavoidable defect created by prescribing kryptok bifocals where one eye was quite different from the other in refraction in the vertical meridian. When, for instance, one prescriped a lens for an individual that had minus two sphere for distance for one eye, and only minus one sphere in the other eye, a difference of a diopter, he was creating a hyperphoria. By using a prism in the lower segment that could not be avoided. In any individual, where there was a difference in the refraction of one eye as compared with the other in the vertical meridian, that difference would manifest itself in the reading segment by about as many tenths of degrees of prism as the difference in diopters. One was artificially creating a hyperphoria which could not be avoided in kryptok lenses as made at present. (Here Dr. Von Der Heydt illustrated the point by the aid of diagrams.)

At the request of the president, Dr. Schneider explained how the lens was ground and described the mechanical methods that were used by opticians in producing it.

ALFRED N. MURRAY, Sec.

ABSTRACTS

H. Weve.—Epidemic Parotitis with Iridocyclitis.—Tydschr. v Geneesk. Feb. 23, 1918.

Weve reports three cases of this disease, where he can exclude, with much greater certainty than Heerfordt could in 1909, tuberculosis, lues and pseudoleukemia; and he accepts on epidemiologic and clinical grounds as cause of the common epidemic parotitis.

It seems contrary to the literature that chronic iridocyclitis should be not a very rare localization of the virus of the epidemic parotitis But this can be explained, as in most cases the iridocyclitis precedes some weeks the appearance of the parotitis. The parotitis is then considered as an intercurrent disease, for which the patient is treated by his family physician; and of which the ophthalmologist in most cases does not hear. Only in rare cases where the parotid swelling remains for a long time has the ophthalmologist a chance to think of a connection.

CASE 1. A 14-year old boy came with a double iridocyclitis to the clinic. The eyes were externally pale. The pupils reacted well, and there were some Descemet spots, fine posterior synechiae, and marked optic neuritis with slightly curved and strongly filled vessels. R. V.=5/5 Temp. in bed (three weeks after the onset) normal. Only once the evening temp. was 37.8° in axilla. Leucocytosis. Tuberculin TR up to 20 mgr. subcutaneously never showed any reaction. On discharge no Descemet spots. In L. only a few fine posterior synechiae and some fine vitreous dust and slight optic neuritis.

Four or five months after the first attack the patient returned with a marked painless double swelling of both parotids. The recurrence came without pain, and at the same time L., which had remained pale, had become strongly injected and painful. Fresh Descemet spots and a distinct optic neuritis were present. The lymphocytosis was somewhat increased, compared with the first attack. Some two months later, while the parotid swelling was still present a nodule formed in the left iris. No more Descemet spots were present. At the same time

some ten fresh Descemet spots appeared in O. D. and a nodule in the chamber angle, which looked somewhat like a beginning gumma. Slowly a double nodular iritis developed, which looked especially menacing in R. Strong increase of the number of Descemet spots, deep blue-red pericorneal injection, edema of the cornea especially down, diminution of V. in R. to about 1/4. Three injections of 20, 15 and 8 cm. subcutaneously of serum from a patient, who had recovered from epidemic parotitis were tolerated without disturbance or reaction. No favorable influence upon the ocular process was noted. The nodules grew in both eyes, the Descemet spots increased. Von Pirquet reaction was again negative. Radium was tried. R. was treated with 5 mgr. during 10 minutes, in 8 weeks 15 times. Fourteen days after the beginning distinct improvement was visible. The Descemet spots were reduced in number and size as against L., which had not received the rays. A month after the beginning the nodules in R. had become smaller, and three weeks still later they were nearly absorbed, the Descemet spots could be counted. Six weeks after the beginning the radium treatment R., which for a year had been refractory to every treatment, was entirely cured. V. after correction=1, 5.

As L. did not progress it also was treated, but to reach a quicker result the sitting lasted 20 minutes, nine in five weeks. This improved also, within 14 days. Within four weeks the large tumor had entirely shrunken and the hundreds of Descemet spots had disappeared except a few. V., which was before the radium treatment 1/3 improved to 3/4. Condition half a year later: R. a few Descemet spots centrally. V=5/4+. L. a number of fine Descemet spots are visible down, optic nerve not sharply defined, V.= 5/4—.

Case 2. Mother of three healthy children, 28 years old. On February 1 peripheral facial palsy on the right side, which was healed three weeks later. A week after the beginning swelling of the left parotid; three weeks after this the right parotid also began to swell. After some two to three months they disappeared slowly. The lacrimal glands were not affected. In the middle of June the patient came under observation. She states distinctly that some weeks before the facial palsy L. had become cloudy. Only five weeks thereafter, therefore about the same time of the right sided parotitis, R. became blurry. In November V. was in each eye=1. Some fine vitreous dust and very fine, partly brown Descemet spots are still present. The strong posterior synechiae did not loosen.

Case 3. A 15 years old girl, had not been sick. L. began to blurr in the middle of April, and became red. A week later the left cheek, and again a week later the right cheek became swollen; and two weeks later R. became inflamed. Four or five weeks after the beginning of the inflammation of L. a left facial palsy appeared, which remained about a month. The menses stayed away during five months, after the beginning of the ocular affection. The painless swellings of the parotids had disappeared after two weeks. The ocular inflammation was not entirely cured after four months; then the condition of both eyes became worse and the patient presented herself at the dispensary. She was taken in the hospital and remained two months. R. being the worst was treated with radium twice a week during 15 minutes, 5 mgr. radium in copper tube with mica-plate. She received 20 treatments. After a few weeks, improvement set in. L. improved spontaneously. Three months after the beginning of the treatment only a small residue remains of the Descemet spots with a rather sharply limited opacity in the deepest corneal layers (=the toxic edema of Straub). A few small vessels go toward this infiltrate. After correction V.=1/4, optic nerve very red. In L. a central group of the Descemet opacities with corresponding deep infiltration, a small deep infiltration medium and down and a few iris vessels, strong optic neuritis corrected V=1/6. [See A. J. O. June 1918. p. 433-4.] E. E. B.

Pacheco Luna. Study of Trachoma in Guatemala. (Guatemala, 1918.)

The author has found trachoma an exceedingly rare disease in Guatemala. In twelve years of practice, he has not been able to find the disease in creoles or natives. All are imported cases, which, he asserts, lose rapidly their contagiousness and do not infect natives, notwithstanding the bad hygienic surroundings and crowding prevalent amongst the people in cities.

He attributes this attenuation of virulence to the climate, but mentions also the fact that in France trachoma is rare, and not transmissible, the poor trachomatous Jews of the Bastille Borough in Paris, enjoying full liberty and never transmitting the disease to relatives.

The same thing happens in Mexico, where true trachoma is very rare. In the reviewer's experience only three in 1,000 of his dispensary cases developed trachoma. This rarity, however, is probably much more dependent on the scarcity of immigration than on climatic conditions. In some places of Mexico where immigration is active the number of trachoma cases increase and the natives are also infected. The same occurs in Argentina, according to Otto Wernicke.

URIBE TRONCOSO.

Lhermitte, J., and Saint-Martin, de. Primary Polioencephalitis with Narcolepsy. Ann. d'Ocul., 1918, v. 155, p. 487.

The authors report three cases appearing during the course of an epidemic in the early part of 1918, generally known as "Lethargic Encephalitis." The predominant features of this disease are ocular paralysis, narcolepsy or somnolence and alterations in the general health. The ocular manifestations are found in the initial stage, either preceding or closely following the somnolence. Unilateral or bilateral inward deviation of the eyeball and ptosis are the most striking ocular symptoms. In the first two cases of the authors, there was almost complete paralysis of all the branches of both motor oculi, altho the different branches were unequally affected. In the third case, the external rectus of each eye was affected. A review is given of the general symptoms and eye findings as shown by the experiences of other authors. The characteristic of the ophthalmoplegias is that they are disassociated and migratory. This, with the somnolence, would indicate a lesion in the peduncular region, that is of the nuclei of the III and VI nerves and possibly their connecting fibers. This has been confirmed by postmortem findings. It is an infectious disease, the agent of which has not been identified. C. L.

Frenkel, H.—Prognosis and Treatment of Ocular Wounds Due to Penetrating Foreign Bodies. — Archives d'Ophtalmologie, July-August, 1918, Vol. XXXVI, p. 193.

The fact that wounds of the globe due to penetrating foreign bodies give a much better prognosis in civil than in military life is due to the fact that in civil life the foreign bodies are, as a rule, single, whereas in military life they are generally multiple. This fact can often be determined by radiography of the eye in situ, but becomes much more apparent when radiography of the enucleated eyes is practised. This explains why in war work enucleation is often found necessary even after an easy and seemingly successful extraction with the magnet. In 59 out of 100 enucleated eyes chosen at random foreign bodies were found; 21 of the 59 showed a single foreign body, 38 more than one, one having more than 17, and 4 metallic dust. Most of these bodies were so small that their extraction was impossible even with the strongest magnets unless by chance the magnet came very close to them. In two cases there remained a second foreign body in the eye after the first had been extracted with the magnet. In spite of its drawbacks the large magnet is the more useful, the small magnet often giving negative results. Sometimes repeated applications of the magnet will be crowned with success; presumably the foreign body gets shifted into a position more favorable for its extraction. M. W. F.

THE EYES OF THE AVIATOR.

If aviation had been achieved thru an evolutionary transition extending over countless generations, like that from the fish to the bird, it would have been attended with the perfecting of physical organization by the weeding out of countless defects, little noticed and of trifling importance while we walk on the earth, but fatal when we attempt to mount into the air. Among such defects, previously little thought of, are some of the eye and vision, that rise to tragic prominence with attempts at flying.

To speak of the air service as "the eyes of the modern army" is to keep as near the truth as figurative statement ever can. Blind Samson, the sport of his enemies, might well represent an army of today without its aviators. And if, by sacrifice of his own existence Samson could inflict terrible punishment upon the enemy, still it was only "schrecklichkeit," not military efficiency.

If salt that has lost its savor is useless, what is to be said of the eye that does not see things that safety requires should be seen? A scotoma, never appreciated as a defect in the field of vision, may hide an enemy until time for effective defense is passed. Color perception only slightly subnormal might make the observer fatally slow to pierce a disguise. A minor defect of motor coördination and balance may be of no importance while a man stands with his feet on the earth, yet it means disaster when attempting a difficult landing.

The experience of war has led to the relaxation of visual requirements in many branches of the service. But for air service it teaches that they should be made, if possible, more exacting, and should be rigidly enforced.

No material relaxation of them is possible without an increase in the proportion of fatalities, which makes those inflicted by the enemy look small in comparison.

The Major in the regular army whose son has a slight macular lesion, and minute relative scotoma with disturbance of muscle balance, never be-

fore noticed, cannot understand why his boy may not gratify his laudable ambition to become a flier.

The Congressman, who does not know the difference between the accommodation of the eye, and that of obtaining a small loan from his bank, does not understand why the government should be put to the expense of a physiologic laboratory like that at Mineola. Yet the Major would be inconsolable for the death of his son in the smash of a bad landing; and the Congressman would declaim most eloquently against the sacrifice of $50,000 airplanes to say nothing of the expense of the training and lives of needed officers thru the temporary disabilities produced by altitude or training in stunt flying necessary for attack or defense in the air.

There is great need for scientific men to acquaint themselves with the facts regarding the physical requirements for safe and successful aviation; and then to exert themselves actively in producing a public opinion that will support rigid requirements for the aviator, and scientific study of all the difficulties he has to meet and overcome. The book on Air Service Medical, elsewhere noticed in this number, should be read and studied by every oculist who wishes to keep in touch with the newest and most suggestive phases of medical thought; and at the same time get a new point of view for the functions and diseases with which he has to deal in his daily practice, and fit himself to perform his educational duty toward the public.

E. J.

RELATIVE SCARCITY OF TRACHOMA ON THE PACIFIC COAST.

Rarely does a writer remark upon the paucity of clinical material; rather is it true that he selects a subject for which he has gathered as many cases as possible.

This writer has been struck with the fewness of trachoma patients whose home is in the Pacific Northwest. This is the more remarkable because our population is easily eighty per cent transplanted from other sections of America, with a great mixture of the foreign element from all parts of the world. Of the latter there are race elements prone to this disease;—the Swedes and Norwegians, those from the Levant, Southern Europe and the Japanese. Odds and ends of peoples are found; even the Spanish-speaking Jews from the Marmora seacoast of Turkey, and as a contrast occasionally an Eskimo.

The coast Indian tribes are not at all afflicted with trachoma, while those east of the Cascade Mountains, and particularly those east of the Rockies, have quite a high percentage of sore eyes from this disease.

The writer finds quite a contrast in the last 10 years of his practice to the two decades spent in the Great Lakes Regions, as regards the prevalence of trachoma in private practice. His recent experience in Army Service corroborates the opinion that the affliction is not only not endemic in the Northwest, but that practically all cases here are imported, few arise de novo, or few contagions result.

We must then ascribe the relative immunity of our inhabitants to the climate, to the absence of dust and flies;—due to the cool, equable and moist climate as well as to the character of the soil, which is mostly a loam upon gravel or hard pan, there being little fine sand or clay to form dust. Then, too, our people live largely out of doors, even during our winter weather.

Conditions are different over the mountains where the intense heat of the summer with its dust and dirt and the rigors of the winter, with the fouler air of house living, give local causes of ocular irritation. Now are these not provocative causes for trachoma? Certainly the refractive conditions with the eye strain are not different here, neither are the other alleged causes of the disease. Thus the writer comes to the conclusion regarding trachoma that the moderate climate of the Northwest Pacific slope is

a favorable factor for its cure; and that these cases do not obtain here as often as elsewhere.

H. V. W.

OPHTHALMOLOGY FOR MEDICAL STUDENTS.

When American Medical Schools granted the M. D. after two courses of five months each; and the clinical teaching consisted of lectures to a hundred or two hundred students, with a patient for a text; or an operative exhibition where a dozen nearest the patient could observe part of the technic; and when the student could graduate without even looking thru a microscope; ophthalmology was supposed to be well treated if it received any attention at all.

The medical course has lengthened from 10 to 36 or 48 months. Clinical teaching includes section demonstrations, ward walks, individual study of assigned cases, and practical hospital interne work. The laboratory buildings are the chief buildings of the medical school, and in fundamental branches laboratory hours exceed those for lectures and recitations. But the improvements in the teaching of ophthalmology have not kept pace with this progress, and are not proportioned to the importance of the subject in its bearings on general medicine.

This teaching of ophthalmology to medical students in general is important to the ophthalmologist from two standpoints. It furnishes the start for his special training in ophthalmology, and it determines the point of view of the general medical profession with regard to ophthalmology, and their ability to coöperate with the ophthalmologist and appreciate the special services that he renders.

An interesting symposium upon such teaching is published in the *Edinburgh Medical Journal* for January, 1919. The writers are, E. Treacher Collins, Freeland Fergus, Wm. G. Sym, and J. V. Paterson, all competent ophthalmologists and experienced teachers. They agree that the time assigned to ophthalmology, "20 meetings," is inadequate; that 32 or 40 are needed, that most of these should be clinical, or demonstrations which might well extend over more than one hour each.

All of these writers agree that certain things of importance in general practice, like ophthalmia neonatorum or glaucoma, should be taught and emphasized. But it is pointed out that only a part of the students, one in five according to Fergus, will profit much by work in refraction.

Collins and Fergus dwell on the need for teaching every medical student to use the ophthalmoscope, Collins enumerates the questions it will settle with regard to general diseases, and its value in training to exact observation. Paterson says it should be taught as early as possible in the course, and used in every clinic in the latter clinical part of the course. Fergus would have the student become as familiar with its use as with that of the clinical thermometer.

It might be urged with even greater force that every medical student should use this instrument for the ophthalmoscopic study of pathology. A particularly weak point in the improved, extended medical curriculum is the wide gap between the study of pathologic changes in the dead body, and the study of symptoms in the living. The ophthalmoscope making possible the study of pathology, day after day, in living nervous, vascular, and connective structures, should be made to bridge this gap between fundamental and practical training; and bring laboratory exactness to the study of symptomatology.

It is a good sign when four such ophthalmologists as those above mentioned are asked to contribute to a series of discussions of general medical education. The proper undergraduate teaching of ophthalmology should be urged by ophthalmologists everywhere, until its importance is appreciated by the whole medical profession.

E. J.

BOOK NOTICES.

Air Service Medical: War Department: Air Service Division of Military Aeronautics. Octavo. 446 pages. Illustrated. Washington, D. C. Government Printing Office, 1919.

This large book, bringing up the medical history of the air service to March, 1919, will be of great interest to the medical profession in general. We can only note here the parts that refer especially to ophthalmology, and certain sections bearing on general function and nutrition that include notable effects on the eye. It is "for educational purposes that the Director of Military Aeronautics deemed it advisable to issue this book. Its object is to set forth Aviation's debt to Medicine, and to make clear the part played by the Air Medical Service in the winning of the war in the air."

This work is sharply divided into three phases, the selection of the flier; the classification of the flier; and the maintenance of the physical efficiency of the flier. In the selection the object was that no aviator should "fail in his mission against the Hun because of discoverable physical defect." The importance of this was not at first appreciated by anyone, and is still not understood by those who have not sufficiently studied the matter. The approximate statistics thus stated are startling. "When it is stated that 2 per cent of the total number of fliers incapacitated for further air service are put out by the Hun, and 8 per cent because of mechanical shortcomings of the airplane, the remaining 90 per cent looms large when it is realized that this proportion represents troubles in the flier himself."

In the light of experience, the minute investigation of the special senses and general physical fitness of applicants for the air service, that have been often adversely criticized is more than justified. Men were rejected, not because they could not fly, but because under the stress of air battle some slight discoverable weakness or tendency would turn the balance against them.

We can safely claim that never before have any large number of men undergone such minute searching and scientific examination as the fliers for the American Army.

Among these examinations the visual and ocular occupy a very important place. In the 67 units established for such examination 176 ophthalmologists took part in the work. The investigation they conducted in every instance covered the following points:

1. History of previous or present eye trouble.
2. Stereoscopic vision.
3. Ocular movements.
4. Pupillary reactions—direct, consensual, accommodation.
5. Intraocular tension.
6. Any visible lesion of the eye.
7. Nystagmus.
8. Field of vision.
9. Color vision.
10. Muscle balance at 20 feet.
11. Visual acuity — distance, near point.
12. Ophthalmoscopic findings with dilated pupil.

The schedule is one that may well be made the basis of any scheme for thoro ocular examination. The illustrations and descriptions here given of the conduct of such an investigation make this work an extremely valuable guide for anyone desiring to perfect himself in methods of ocular diagnosis.

Of the men presenting themselves as applicants for the air service, 29.3 per cent failed to pass the physical examination; and of these 5.9 failed in the eye examination alone; 7 per cent in two tests, and 8.6 per cent in three or more tests. Practically 50 per cent of those rejected failed to meet the eye requirements. Of 59 thus rejected for eye defects, 33 had low visual acuity, 10 had defective color vision, 7 imperfect muscle balance, 5 lacked stereoscopic vision, and 3 were eliminated because of the ophthalmoscopic evidences of disease.

The effects of altitude or of oxygen deficiency on ocular functions, particularly visual acuity, accommodation, the field of vision, and motor coördination

is so important, and so much light has been thrown upon the subject by the laboratory researches carried on in connection with the Air Service Medical, that it will be considered separately in a later issue.

It is rarely that a volume of solid scientific worth contains so much of dramatic interest and romance. It is worthy the careful perusal of anyone who can secure it.

E. J.

Revista Cubana de Oftalmologia. Published quarterly. Dr. Francisco Maria Fernandez, Editor. Dr. Jesus M. Penichet, Secretary. Havana, Cuba. Subscription Price, $6 per year.

It is not often that a new ophthalmic journal has a chance to fill a real and long felt want; but this one has that opportunity and uses it admirably. The first number is put out as a double number covering the first half of the year 1919, and consists of 226 pages, of which 14 are given to a biographic section, 112 pages to original papers, and the remainder to progress of ophthalmology and reviews of ophthalmic journals and societies, with notices of deaths, and miscellaneous items.

The biographic section contains 6 biographies, each accompanied by a half tone portrait. Of the 24 original papers, 2 are illustrated. The paper used and the press work are good; so that the Revista Cubana makes a better appearance than any ophthalmic journal heretofore printed in the Spanish language. We know enough of the work of Drs. Fernandez and Penichet to feel sure that this will be an addition of real value to the ophthalmic journals of the world. Spanish-speaking countries, especially those of America, have recently manifested an active and productive interest in ophthalmology. Thru this channel they will have something of real worth to offer to the general store of our literature.

E. J.

Section on Ophthalmology, American Medical Association. Presession Volume for 1919. Edited by the Secretary, A. E. Bulson, Jr., pages 307. Illustrated.

This volume, altho printed and circulated, is not published. It is distributed free to those who have registered as members in attendance at a meeting of the Section within the last five years. It is the most valuable piece of free ophthalmic literature we know of. On the other hand, those whose papers are thus distributed have 1,000 or 1,200 reprints of their papers sent to the most appreciative list of readers, for much less than they could get the same number of reprints sent any other way.

It might be objected that this duplicates the volume of Transactions to appear later. In a way it does; but it adds greatly to the value of that volume by bringing out discussions of much higher value than could be had without this; and those discussions will be a most valuable part of the Transactions.

E. J.

BIOGRAPHIC SKETCHES

Thomas Hall Shastid

SUPERIOR, WIS.

Urban S. Bird. An ophthalmologist and oto-laryngologist of Tampa, Florida, well known thruout the South. Born in 1867, he received the medical degree at Tulane University, New Orleans, in 1895, and at once settled in Tampa. Ten years later he went again to New Orleans, where he studied ophthalmology and oto-laryngology for two years. Returning to Tampa he practiced there as ophthalmologist and oto-laryngologist for the remainder of his life. He was a member of the American Laryngological, Rhinological and Otological Society. and a surgeon of U. S. volunteers during the war with Spain. He also held a lieutenant's commission in the American Army during the Great War, and was honorably discharged Dec. 5, 1918. He died Jan. 11, 1919.

WILLIAM CHEATHAM. One of the best known eye and ear specialists in Kentucky. Born in Taylorsville, Ky., June 6, 1852, son of William H. and Elizabeth (Vandyke) Cheatham, he removed with his parents to Louisville while still a mere boy. In 1873 he received the degree of A. B. from the Kentucky Military Institute at Frankfort. Three years later he received the medical degree at the University of Louisville.

Going to New York, he became an intern in the Manhattan Eye and Ear Hospital and at the same time a private pupil of Dr. Cornelius Rea Agnew, that famous teacher of so many excellent ophthalmologists. Having completed his course under Dr. Agnew, he studied his specialties further in London, Paris, and Vienna.

Returning to Louisville, he began at once to practice as ophthalmologist and oto-laryngologist, and soon had an excellent practice. He was promptly given a lectureship at the University, and, soon after, the full professorship. At the time of his death he was Professor Emeritus of Ophthalmology, Rhinology, Otology and Laryngology. He was a member of the American Ophthalmological Society, and a Fellow of the American College of Surgeons.

Dr. Cheatham married, Oct. 2, 1879, Miss Nellie Garrard, who died a few years ago.

In the latter part of 1917 Dr. Cheatham began to notice a certain recurring weakness of the heart. Early in the present year the attacks became more serious, and, in the afternoon of April 3, 1919, the doctor left his office, walked into the corridor of St. Joseph's infirmary, and said to the sisters who greeted him, "I have come over to die." Three hours later he had expired. Dr. Cheatham was survived by a daughter, Mrs. Joseph R. Baker, of Evanston, Ill., and a sister, Mrs. E. D. Borne, of Taylorsville.

Dr. Cheatham was a man of great nervous energy and a tireless worker. He was often said to have treated gratis more patients than probably any other doctor in Kentucky. It is further said of him that he secured a reduction in the price of optical goods for those for whom he had prescribed, and who could not afford to pay the full prices. His love for animals was very pronounced, and he had many pets. Among these were three little rat terriers, Chita, Minnie, and Cricky, which he himself would always feed and on which he lavished much attention and care. He used to say that they helped fill the void in his life caused by the loss of loved ones. He had also a number of parrakeets, which whistled and chattered in a cage in his reception hall.

As to further characteristics a friend has written: "He was a man fond of good reading, of the classics, and he had many beautifully bound works in which he took delight. A collection of Hogarth engravings also was one of his possessions in which he took much pride. His Chestnut street office and home was filled with a number of curios, some of great historical value. Many of them were Civil, Mexican and Revolutionary War relics. He had a number of foreign weapons, some of ancient date, many of which had been used by noted persons. Never did he fail to entertain a visitor or patient with some interesting things which he had picked up here or there on his travels or which had been given him by those who knew of his hobby. Some valuable cloisonne vases were among his collection." Yet another friend has written: "In his day the most distinguished eye, ear, nose and throat specialist of the Southern country, Dr. Cheatham was never too busy to attend a patient, nor was a patient ever too poor to command his most scrupulous service. He believed that the art he was born with and the science he acquired through years of faithful study belonged to mankind, and so he used it. . . . To the public, there was never a truer friend; to his patients, there was never a less sordid healer; to his friend, there was never a finer comrade than Dr. Cheatham. The light fades from his tired eyes to live forever in the recollection of those who loved him."

George Anderson Cubbison. A well known ophthalmologist of Erie, Penna. Born in 1863, he received the medical degree at the Western Pennsylvania Medical College, Pittsburgh, in 1897. He died at his home Dec. 21, 1918, after a short illness from pneumonia. He was a Knight Templar, a Shriner, a member of the Temple Band. He is survived by his widow and two sons.

Mitchell Mikkelsen. An ophthalmologist and oto-laryngologist of Wells, Minnesota. He was born in Dane County, Wis., July 27, 1850, son of Knute and Caroline (Erickson) Mikkelsen. At the age of 22, in 1872, he homesteaded 160 acres of land in South Dakota, where, on a number of occasions, he had serious difficulties with the Indians. Later he became a herder of the Texas cattle which were owned by the U. S. Indian Agency nearby, and, in this way, was enabled to save the money which gave him a medical education. In 1877 he graduated at the College of Physicians and Surgeons, at Keokuk, Iowa, and in 1884 at the College of Physicians and Surgeons of Chicago. For twenty-seven years he practiced at Wells. He married on Oct. 22, 1879, a Miss Ella Heffron. After her death he married Miss Mary Perrigode Runo, a lady of French extraction. She died about fifteen years ago. For the last few years Dr. Mikkelsen had been living in retirement and in very feeble health. He died Jan. 8, 1919, from pneumonia.

Ellsworth Hazen Noble. A homeopathic ophthalmologist and oto-laryngologist, of Elmira, New York, well known locally. Born in 1866, he graduated from the Columbia College of Pharmacy in 1886 and from the New York Homeopathic Medical College in 1890. For about twenty years he practiced in Elmira. He died at his home in Elmira March 6, 1919, from acute gastritis, and was survived by his widow, who, before her marriage to Dr. Noble, was Miss Florence Loughhead, of Elmira.

Samuel Leo Oren. A young ophthalmologist and oto-laryngologist of Lewistown, Ill., who gave much promise. He was born at Laporte, Ia., on Oct. 1, 1879. Having attended Upper Iowa University at Fayette, Ia., he entered the Barnes Medical College, at St. Louis, Mo., at a very early age, and there received his medical degree in 1899, being only twenty years old. Later he took a year's graduate course in the medical department of the Iowa State University, at Iowa City, Ia.

For a time he practiced at Davis, Ill., but removed to Lewistown on Jan. 1, 1903, where he formed a partnership with his father, Dr. S. A. Oren. He married, in 1904, Miss Helen A. Wise, of Davis, Ill. He received his commission as first lieutenant in the medical corps of the U. S. Army on Aug. 18, 1917, and embarked for overseas in July, 1918. He died on duty in France, Oct. 9, 1918, presumably of collapse following ambulatory typhoid fever, and was buried with military honors in an American graveyard at Clermont-Ferrand, France.

James Morrison Ray. A well known ophthalmologist of Louisville, Ky. He was born Aug. 10, 1860, at Bloomfield, Nelson Co., Ky., son of Isaac N. and Ruth (Bodine) Ray, and nephew of the celebrated Dr. James M. Bodine. He received the medical degree at the University of Louisville in 1882, and, after a brief period of general practice, went to New York, where he studied the eye, ear, nose and throat in the Manhattan Eye and Ear Hospital. While in this institution he was assistant to the famous Dr. Cornelius Rea Agnew.

Returning to Louisville in 1885, Dr. Ray settled in that city as ophthalmologist and oto-laryngologist, and was immediately afterward appointed a clinical assistant in ophthalmology, otology, and laryngology in the Medical Department of the University of Louisville. He afterwards studied the eye, ear, nose and throat in Paris, London, and Vienna, and, returning to Louisville, was awarded the full professorship of opththalmology in his alma mater. When the various Louisville schools merged with the Medical Department of the University, Dr. Ray was elected chairman of the medical faculty, a position which he held till his

death. He was ophthalmic surgeon to the Louisville City and to the SS. Mary and Elizabeth Hospitals, a member of the American Ophthalmological Society, a delegate to the International Medical Congress at London in 1913, and a Fellow of the American College of Surgeons. He was a Baptist.

Dr. Ray never married. He died in Louisville, Oct. 11, 1918, of chronic Bright's disease, survived by only two near relatives, sisters—Mrs. Sam Fulton, of Florida, and Mrs. Kate Wilson, of Louisville.

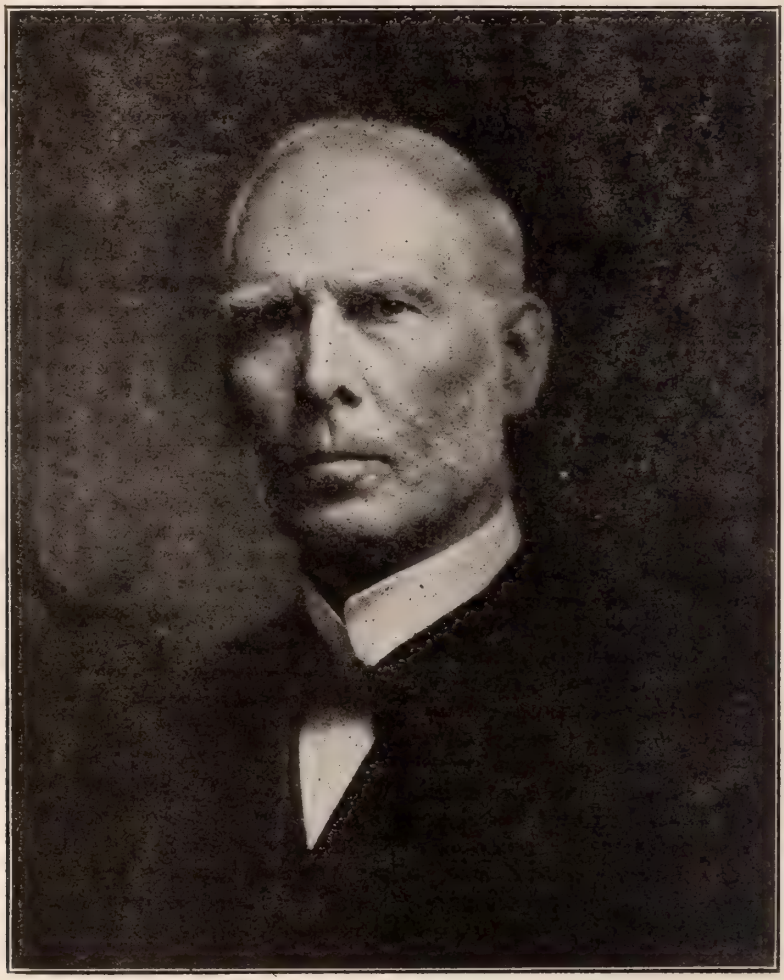
Dr. Ray was a large, stout man, of a fair complexion, and with gray eyes and brown hair. He wore as a rule a mustache. Concerning his mental characteristics a friend has written as follows: "It was said of him that his assiduity to and love for his profession served as an inspiration to the younger generation of physicians in Louisville. A gruffness of manner, which, however, was only a cloak which concealed a generosity of heart unequalled in Louisville. This, it was said, was the outstanding feature of his unique personality. Even to those he loved most, this characteristic was most apparent, and it was something which those who met him casually never failed to remark. This trait of gruffness concealing over-generosity, as it was characterized, was something to which hundreds of persons to whom he had given the best of his skill in the alleviation of disease and suffering might testify. Many of these never received a bill from him. Others, it is said, were made everlastingly grateful by a modest charge from an unusually able specialist.

Richard Andrews Reeve was a prominent Canadian ophthalmologist. Born in Toronto in 1842, son of William R. Reeve, he received the degree of B. A. at Toronto University in 1862, winning the silver medal in Natural Sciences. In 1865 he received the M. D. at Queen's University, Kingston, and, again, in 1889, at the University of Toronto. He became a Fellow of the Royal College of Physicians and Surgeons in 1866.

From 1865 until his death he seems to have practiced continuously in Toronto, excepting when engaged in study for the *ad eundem* degree. In 1867 he began to devote his attention exclusively to diseases of the eye and ear.

For many years he lectured on ophthalmology in the Toronto School of Medicine, and, from 1885 until his death, on ophthalmology and otology in the University of Toronto. In 1890 he was chosen dean of the medical faculty, a position which he resigned in 1908. He was made chief of the eye department in the Toronto General Hospital in 1907. He was also, for a time, a member of the Toronto University Council and of the Board of Regents of Victoria University.

Dr. Reeve was once president of the Canadian Medical Association, and was president of the British Medical Association when it met at Toronto in 1906. He was a delegate to the British Medical Congress in 1910 and from 1904-7 president of the University Alumni Association. He was also a Fellow of the American College of Surgeons.



Dr. Reeve died suddenly on Jan. 27, 1919, at Harbord Street and Spadina Avenue, Toronto. He was an active member of the Central Methodist Church. Mrs. Reeve had died about two years before, and the only surviving relatives are two sisters and a brother, Dr. J. Reeve, of Deland, Florida.

Concerning the personality of Dr. Reeve, a writer in "The Canada Lancet" gives us the following: "His was one of those quiet, subtle influences that took a hold of one; and once it laid hold, grew. No one ever heard a rude or coarse remark fall from his lips. He was most deferential to the opinions of others, ever seeking to promote the welfare of his profession, always ready to act in any capacity, his confrères sought his aid, and always displaying a keen insight into the questions brought before him. His humor, too, was of the most delightful character . . . Dr. Reeve was both an example and an inspiration. He be-

longs to the future as well as the past."

ABRAHAM SACHS. An eye, ear, nose and throat specialist of San Antonio, Texas. Born in Austria, Mar. 1, 1872, he received his medical degree at the Miami Medical College, Cincinnati, in 1900. At first he practiced in Cincinnati, then in Chicago, but at length, in 1906, removed to San Antonio. He was a brother of Harry Millard Sachs, a noted actor. He was asphyxiated at his residence on the evening of Jan. 19, 1919, by gas fumes in his bath room.

CHARLES HENRY WEINTZ. An ophthalmologist of Cincinnati, O. Born in 1870, he received the medical degree at the Miami Medical College, Cincinnati, in 1909. He was assistant to the chief of the nose and throat department of the base hospital at Chillicothe, O., under Dr. C. R. Holmes. Dr. Weintz died at Camp Sherman, Oct. 14, 1918, of pneumonia.

Richard Andrews Reeve, 1842-1919.

CORNELIUS WILLIAMS. A well known ophthalmologist of St. Paul, Minn. Born in Kentucky in 1848, he removed in 1864 to Minnesota but later returned to Kentucky. His medical degree was received at the College of Physicians and Surgeons in the City of New York in 1874. Having studied ophthalmol-

ogy and oto-laryngology and practiced both these specialties in New York City for a number of years, he removed in 1882 to St. Paul. In 1901 he was president of the Ramsey County Medical Society. At some time in his career he was admitted to the Minnesota bar, and, on a number of occasions, conducted his own lawsuits—each time, it is said, successfully. He died at St. Luke's Hospital, St. Paul, Dec. 30, 1918, aged 70 years. He was survived by one son.

Jesse Sydney Wyler. A celebrated ophthalmologist of Cincinnati, O., who died young, but who had given much promise of great things. He was born at Cincinnati, Sept. 7, 1879, son of Isaac A. and Adelaide (Lowman) Wyler. His medical degree was received at the Miami Medical College in 1904. After serving as interne in the old City Hospital, he continued his studies in Europe. Returning to Cincinnati, he soon was widely known as a skilful operator. He was elected to the staff of the Cincinnati General Hospital in 1910 and to the staff of the Jewish Hospital in 1912.

Dr. Wyler was of medium height, smooth-faced, of a ruddy complexion and with bright brown eyes and hair. He was gay and genial, very fond of children, a collector of books, a Republican, not a religionist but a Jew by birth. He married, Nov. 30, 1908, Miss Florence Iglauer, by whom he had two children. He died at Cincinnati, Oct. 28, 1918.

Concerning the personality of this very able man, we are glad to quote the following from Dr. Derrick T. Vail, who knew him intimately: "Dr. Wyler was one of those enthusiastic, active, able and gifted men who studied ophthalmology not of necessity, for he came from a family possessing ample means, but because he was ambitious and had a natural desire for a scientific and professional career. He did not, therefore, declare himself an ophthalmologist or begin practicing before he was properly equipped.

"He possesed a fine education, spoke the German and French languages fluently, also had a reading knowledge of Spanish and Italian. He was actively connected with the American Journal of Ophthalmology on the staff of collaborators. Dr. Wyler enjoyed the high esteem of a wide circle of friends both in the profession and out of it. His mind was overflowing with information for he was a keen observer, a good student and had strong convictions for or against the many ophthalmological problems. He was fond of an argument and always believed he was right but was never obnoxious in his manner. He was a very skilful operator. His methods were largely of the Viennese school.

"He was of medium height and since he was approaching forty was beginning to show some of the increased heft of body. He had a high forehead, a strongly intellectual countenance, a winning smile and an ingratiating manner which distinguished him.

"His prewar admiration for the Vienna and Berlin schools of ophthalmology was very great. After our country became involved in the war, however, Dr. Wyler's patriotism and loyalty to our country were very keen and genuine. President Dabney of the University of Cincinnati has testified he died in the service of our country.

"He had a very large and select practice, which however did not in the least prevent his giving full time to his hospital clinic which he thoroughly enjoyed. He was very kind and liberal to the poor, and would give them his best time and services without stint. He was just rounding into the climax of a glorious career when stricken with pneumonia following influenza."

[Note.—Dr. Charles O. Zahn, noticed in this department in the February number, as we have been informed, was not an ophthalmologist.]

NEWS ITEMS

Personals and items of interest should be sent to Dr. Melville Black, 424 Metropolitan Building, Denver, Colorado. They should be sent in by the 25th of the month. The following gentlemen have consented to supply the news from their respective sections: Dr. Edmond E. Blaauw, Buffalo; Dr. H. Alexander Brown, San Francisco; Dr. V. A. Chapman, Milwaukee; Dr. Robert Fagin, Memphis; Dr. M. Feingold, New Orleans; Dr. Wm. F. Hardy, St. Louis; Dr. Geo. F. Keiper, LaFayette, Indiana; Dr. Geo. H. Kress, Los Angeles; Dr. W. H. Lowell, Boston; Dr. Pacheco Luna, Guatemala City, Central America; Dr. Wm. R. Murray, Minneapolis; Dr. G. Oram Ring, Philadelphia; Dr. Chas. P. Small, Chicago; Dr. John E. Virden, New York City; Dr. John O. McReynolds, Dallas, Texas; Dr. Edward F. Parker, Charleston, S. C. Volunteers are needed in other localities.

DEATHS.

Emmet V. Ball, of Atlanta, Ga., of heart disease, aged 48 years.

Edward W. Dean, of Pittsburgh, Pa., of pneumonia, aged 69 years.

Mortimer Frank, of Chicago, of cerebral hemorrhage, aged 44 years.

The death is announced of Sir James MacKenzie Davidson, the pioneer of applied radiology in its relation to ophtholmology, at the age of 63. He was at one time ophthalmic surgeon to the Royal Infirmary of Aberdeen. Later, in London he invented the precise method of localization of foreign bodies in the orbit, by means of the X-ray.

The recent death of Dr. A. J. Stewart, of Provo, Utah, is announced; age 46.

PERSONALS.

Dr. Duverger, Ophthalmologist to the Limoges Hospital, France, and professor in the School of Medicine, is assigned to take charge of the Ophthalmic Faculty at Strasbourg.

The editor of this page recently spent six weeks in California. Several things were indelibly impressed upon his memory. One was that the California oculists are a royal lot of fellows. Another was that California is a delightful place in which to spend a vacation, so fascinating that if April and May are fair samples of their climate, it will be only a matter of time until the state will be too small to hold the population.

Dr. Frank C. Parker, Norristown, Pa., has succeeded Dr. W. C. Posey in the position at the Wills Eye Hospital, Phila., formerly held by Dr. Posey.

COMING MEETINGS.

The Pacific Coast, Oto-Ophthalmic Society will meet at San Francisco, August 4-7.

The Colorado Congress will be held in Denver, August 4-5, and will include both ophthalmic and oto-laryngologic papers and discussions.

The American Academy of Ophthalmology and Oto-Laryngology, will meet at Cleveland, Ohio, Sept. 1-3.

The Oxford Ophthalmological Congress, Oxford, England, July 10-12.

MILITARY NOTES.

Lieut. Col. Nelson Miles Black of Milwaukee has received his discharge from the Army.

Dr. Frederick E. Woodruff of St. Louis has been discharged from the Service.

Dr. H. H. Stark has been discharged from the Medical Corps of the United States Army and has resumed his practice at El Paso, Texas.

Lieut.-Col. Gustavus I. Hogue, of Milwaukee, Wisconsin, writes from Paris, France, that he expects to return soon to America.

Lieut. Col. Sir James Barrett, in the British Service, has returned to his home in Melbourne, Australia.

Col. Walter R. Parker, who was in charge of the department on the Surgery of the Head, at Washington, during our entire period in the war, has been discharged from the Service and has resumed his practice in Detroit.

Dr. Harry Vanderbilt Wurdemann, Seattle, Washington, has been released from army service, as chief of the Eye, Ear, Nose and Throat Section of the Base Hospital, Camp Lewis, Washington, and has returned to civil practice.

Dr. J. W. Thompson, who has been connected with Evacuation Hospital Number 17, located at Vladivostok, Siberia, has returned to Pueblo, Colorado, where he will resume the practice of ophthalmology, in association with his brother, Dr. H. M. Thompson.

Dr. Chas. A. Bahn of New Orleans, Ophthalmologist with Base Hospital 24, Tulane University, is one of the few members of the Unit who are still in France. He has recently been made major and is detailed to the Army Educational Commission in Paris.

Capt. J. M. Shields has been discharged from the Service and will locate in Denver and confine his practice to ophthalmology. He was Ophthalmologist to Base Hospital Number 102, which was assigned to duty with the Italian Army.

Capt. C. E. G. Shannon, an associate of Dr. Howard Forde Hansell, Professor of Ophthalmology, Jefferson College of Philadelphia, received his discharge from Government Serv-

ice April 28th, and has resumed his practice at 1633 Spruce street.

Lieut. Col. de Schweinitz of Philadelphia was returned from Government Service on April first and has resumed private practice at 1705 Walnut street. On April twelfth Dr. de Schweinitz received his commission as Colonel in the Medical Section of the Officers' Reserve Corps, U. S. A.

Surgeon General Merritte W. Ireland was the guest of honor at a reception given under the auspices of the Philadelphia Medical Club at the Bellevue-Stratford Hotel on Friday evening, April 18th, which was attended by five hundred medical men. The reception was preceded by a dinner at the Union League, given in honor of General Ireland by Dr. G. Oram Ring, President of the Club.

Casey A. Wood has been made a full Colonel but he takes the honor so gracefully that his friends still continue to call him "Casey" as of old. A recent visit to him at Palo Alto, California, found him buried in his literary work, but ready to lay it aside long enough to show us the beautiful country in which he is working. He knows the name of every tree, shrub, flower and bird in and about Palo Alto, and it was a rare pleasure to have him to point them out.

Major George F. Suker, until recently in charge of the Eye, Ear, Nose and Throat Service at the Walter Reed General Hospital has resumed private practice at 25 E. Washington, Chicago.

Lieut. W. E. Carson, formerly in charge of ophthalmology at the U. S. N. Hospital, Great Lakes, has been ordered to inactive duty.

Lieut. Col. J. M. Farrell, head of the Spanish-American War Veterans, has returned from France with Base Hospital No. 81.

Major Ira H. Dillon, Bucyrus, Ohio, formerly Chief of Section of Surgery of the Head, Camp Bowie, Texas, has been discharged from service.

SOCIETIES.

The Pacific Coast Oto-Ophthalmological Society will meet at San Francisco August 4, 6, 7. The headquarters will be at the St. Francis Hotel. Dr. Cullin F. Welty is president and Dr. A. S. Green, secretary. A very interesting program has been prepared and a good time generally is predicted.

Dr. Samuel D. Risley has been invited by the special section of the Ohio State Medical Society to present the address in Ophthalmology at the meeting of the section, occurring May 6th, 7th and 8th, at Columbus, Ohio. Dr. Risley will be the guest of honor at a dinner given by Dr. John Edw. Brown at the Columbus Club, during his visit to the Middle West.

On May 15th last the Buffalo Ophthalmological Club had its last meeting during the season. After a subscription dinner, Dr. J. G. Dwyer, the guest of honor, gave a paper under the title, "The Relative Importance of the Teeth, Tonsils and Intestinal Tract in the Production of Focal Infections of the Eye with Especial Reference to the Intestinal Tract." It seems that Dr. Dwyer has made a step forward in elucidating many hitherto very obscure ocular conditions which baffled our therapeutists. The members present, twenty-five, including some out-of-town guests, enjoyed the presentation very much, and a lively discussion showed their interest.

At an interesting program of the Eye, Ear, Nose and Throat Section of the Illinois State Medical Society, which met at Peoria, May 20-22, papers were read by Dr. Willis O. Nance, of Chicago, on "Serpiginous Ulcer of the Cornea"; Dr. H. H. Brown, on "Various Types of Myopia"; Dr. A. L. Adams, Jacksonville, on "The Illinois Institution for the Blind"; Dr. H. W. Woodruff, Joliet, on "Glaucoma"; Dr. John R. Hoffman, on "Binocular Cataract Operations"; Dr. P. C. Matheny, Galesburg, on "Is Malaria an Etiologic Factor in Iritis"; Dr. Alfred N. Murray, Chicago, on "Iritis"; Dr. T. Faith, Chicago, "Early Extraction of Traumatic Cataracts"; Dr. E. R. Crossley, Chicago, "Eye Involvements Following Focal Infections"; Dr. E. E. Edmondson, Mt. Vernon, "Radium in Eye, Ear, Nose and Throat Diseases."

MISCELLANEOUS.

An interesting account of his ophthalmological service in the British army is given by Derby. He found among the alien labor companies that among several thousand Egyptians, nineteen per cent had trachoma; and in upwards of 100,000 Chinese, nine per cent were similarly affected.

After an interval of three years the examination for the Diploma in Ophthalmology at Oxford is to be resumed. The examiners appointed for this year are Dr. G. Mackay of Edinburgh, and Lieut.-Col. A. H. Elliot of London.

Because of their superior sense of touch, Fred F. Bulotin and his wife, both blind, were sworn in yesterday as civilian aids at the Fort Sheridan hospital. Their work will be to massage wounded soldiers. This is the first time in the history of medical reconstruction blind persons have been employed in army hospitals.

The management of the Archives d'Ophtalmologie announces that for the year 1919 the journal will be issued only bi-monthly; but in 1920 they will resume their monthly publication.

The last News Letter published by the National Committee for the Prevention of Blindness shows a widespread interest in the passage of laws by many states for the prevention of ophthalmia neonatorum and trachoma. Several states have Commissions for the Blind which are doing excellent work. The Field Secretary of the National Committee is out on an educational campaign to see that the laggard states are brought into line in these modern methods of ocular prophylaxis.

OPHTHALMIC LITERATURE

These lists contain the titles of all papers bearing on Ophthalmology received within the preceeding month. These titles are all in English, some of them modified to indicate more clearly their subjects. These subjects are grouped under appropriate heads, the succession of groups being the same from month to month. In the group the papers are arranged alphabetically usually by the name of the author in heavy-face type. After the subject of the paper (Ill.) indicates the number of illustrations. (Pl.) the number of plates, and (Col. pl.) colored plates illustrating the article. (Abst.) shows that it is an abstract of the original article. (Bibl.) tells that the paper is accompanied by an important bibliography. (Dis.) means that a discussion of the subject is published with it. Under Repeated Titles are indicated additional publication of papers already noticed. To secure the earliest possible notice writers may send copies of their papers, or reprints, to 318 Majestic Bldg., Denver, Colorado.

DETACHMENT OF RETINA IN TOXEMIA OF PREGNANCY. (CLAPP)

AMERICAN JOURNAL OF OPHTHALMOLOGY

Vol. 2 JULY, 1919 No. 7

DETACHMENT OF THE RETINA IN ECLAMPSIA AND TOXEMIA OF PREGNANCY.

C. A. Clapp, M. D., F. A. C. S.

BALTIMORE, MD.

This paper reports a series of cases seen in Maternity Hospitals (case VI in Johns Hopkins) of Baltimore in a period of sixteen months; representations of the fundus appearances presented in each of the twelve eyes.

While lesions of the eye, extending thru all of the different tissues from the conjunctiva to the optic nerve have been reported with more or less frequency in albuminuria of pregnancy and its allied conditions, it is extremely rare to find any mention of detached retina. Of the various text books upon the eye, Weeks[1] mentions its occurrence but not its frequency; Parsons[2] Pathology of the Eye, under heading of pregnancy, does mention retinal detachment as being occasionally present; and under bibliography refers to an article by Del Zoppo and Soli[3] in which they call attention to the rather close association between genital conditions and eye lesions, and cite a report by Baduel[4] of a woman who had a small detachment of the retina in five succeeding pregnancies, with complete reattachment following each delivery.

De Schweinitz[5] speaks of the changes in general being a widespread "neuroretinitis with hemorrhages and exudates. Martin Cohen[6] reports a case of double detachment in a colored woman of twenty-six, which showed two discs below each nerve head, a typical detachment of the retina. One week later the detachments were much less in extent and eventually reattached completely. Rochon-Duvigneaud[7] claims that some depreciation of vision of permanent nature occurs in 13.33 per cent of albuminuric cases, and that retinal detachment is of frequent occurrence. The Encyclopedia of Ophthalmology says "This is a very rare lesion and probably due to long, difficult labor. Chance[8] believes that these albuminuric cases are not nephritic, as the kidney does not show an inflammation; but a degeneration of retinal epithelium, while ophthalmoscopically neuro-retinitis with hemorrhages and exudates are seen. He makes no mention of retinal separation. While other cases are undoubtedly on record I have been unable to locate them.

I have examined the eyes of practically all of the albuminuria and toxemia cases, occurring in the past fourteen years at the Maryland Lying-In Hospital, and have not observed detachment of the retina until recently. Six cases have presented themselves since December 1917, whose histories briefly are as follows:

Case I.—R. W. (white), age 35. Second pregnancy.

Family history: Father died at forty-five from nephritis; one sister died at twenty-nine from diabetes; one brother died at thirty-one from some kidney trouble.

Present history: Had pronounced edema of legs at sixth month of pregnancy which became gradually worse. On December 17, 1917, vision became dim and on the evening of the 19th she went to bed with headache and vomiting. She was seized with a convulsion about midnight, having eleven convulsions before entering the hospital at 4

a. m., and followed by five within the hospital.

Upon admittance patient's tongue was much swollen, with presence of general edema. B.P. 180/110. Child was delivered still born at 11 a. m. Urine showed presence of albumin without casts.

I first saw the patient at 2 p. m. on December 20, 1917, making the following notes: "Patient has been getting morphin and pupils are contracted, so that it was necessary to dilate pupils before examining fundus. Examination by direct method shows in O.D. general edema of retina, with dark prominent veins, especially above nerve head, with some exudates and hemorrhages, and with appearance of flat detachment of retina below; but patient very restless during examination. O.S. shows general retinal edema but no exudates or hemorrhages." Patient was put on general eliminative treatment, hot packs, etc.

December 22, 1917, direct examination with dilated pupils shows large typical detachment of retina above and one below in right eye, with marked edema of retina, while left eye shows large detachment below disc. See Plate X, A, and Fig. 1.

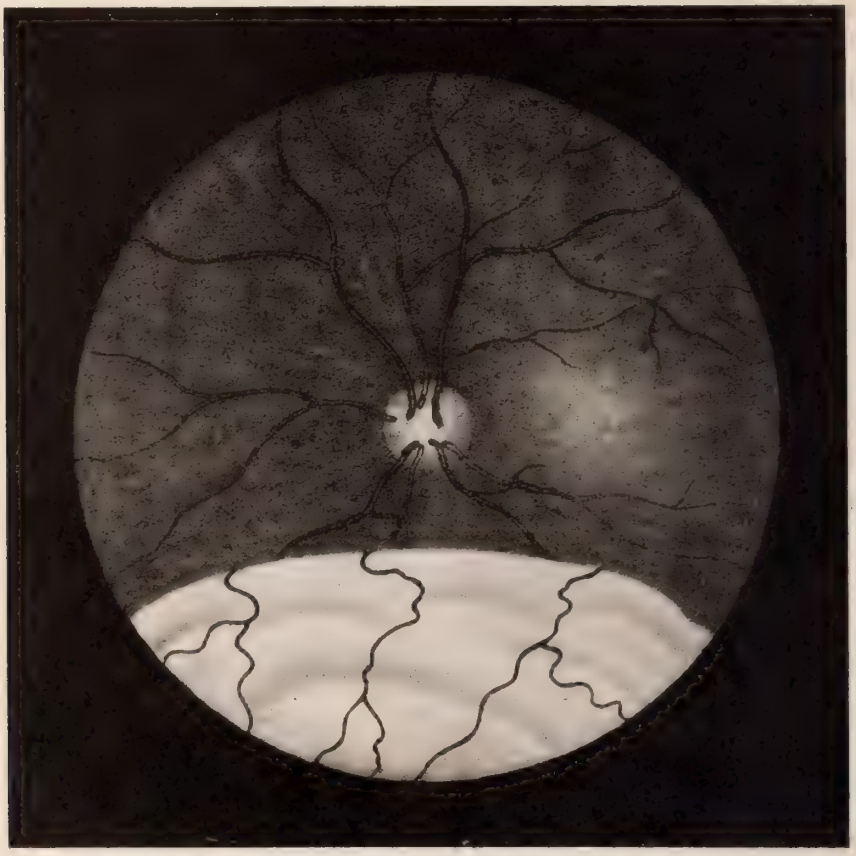

Fig. 1. Case I. Left eye. Retina detached below.

December 27, 1917, with undilated pupils no detachment could be made out above in O.D., and both lower detachments seem to be lessening.

December 29, 1917, pupils dilated. Upper detachment in O.D. has entirely disappeared, while lower one is regaining fundus reflex. O.S. shows greater elevation than right with few hemor-

rhages above macula and general retinal edema with disturbed choroidal pigment.

January 1, 1918, pupils somewhat dilated but react to light. Both lower detachments appear as flat elevations with entire disappearance of hemorrhages and exudates.

February 25, 1918, examination at office showed slight pallor of each nerve with numerous pigmented areas thruout fundi, especially pronounced near right macula; no raised retina. Vision: Right eye, +0.50 = 20/50; left eye, +0.50 = 20/70.

March 23, 1918, fields normal: no change ophthalmoscopically. Vision: Right eye, 20/30—; left eye, 20/20—.

Fig. 2. Case II. Left eye. Retinal hemorrhages and exudates, and detachment below.

Case II.—I. P., (white), age 31.

Family and past history, negative.

Present history: Has had normal pregnancy until five weeks ago, when she began having some disturbance of vision which has gradually become worse. Patient entered hospital March 28, 1918, and was delivered on the 29th; child cyanosed. Blood pressure on entering 180/120, with pulse rate of 120; Wassermann negative. Functional kidney test on April 26, 1918, showed 50 per cent in first hour and 25 per cent in second hour. April 10, urine showed albumin trace. Child died of inanition on April 4, 1918. Pulse on entering hospital 125, on leaving 90. Blood pressure 150/115. Clinical diagnosis was eclampsia, with chronic interstitial nephritis.

Eye examination April 1, 1918. Direct ophthalmoscopy with dilated pupils showed swelling of each nerve head, marked fullness and tortuosity of retinal vessels, pronounced retinal

edema. Three disc diameters below each nerve head is a large classical detachment of the retina, being a little larger in the right eye. Plate X, B.

Examination of eyes on April 6, no change was seen. April 13, 1918, same condition as at first examination, with the addition of numerous exudates and hemorrhages about right nerve and left more elevated than at first. April 16, 1918, detachment in R larger with increase of tortuosity of vessels and also hemorrhages and exudates. See Plate X, B, and Fig. 2. April 23, 1918, no noticeable change with exception of a ½ star-shaped figure at temporal side of right macula and also at nasal side of left macula. April 27, 1918, no change in ophthalmoscopic picture.

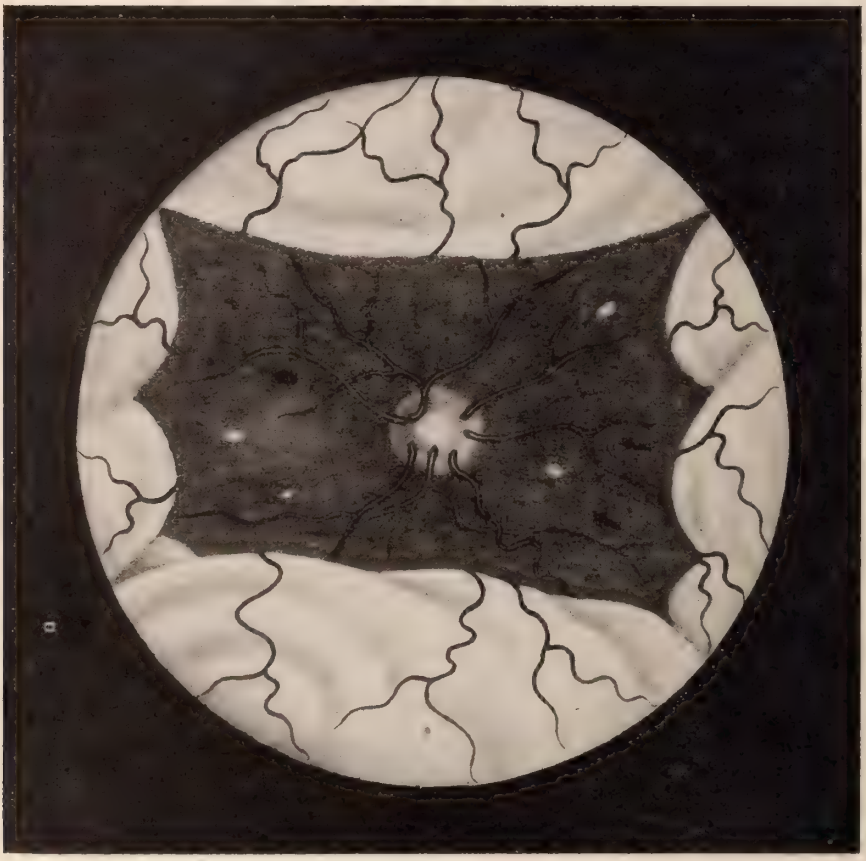

Fig. 3. Case III. Right eye. Retinal detachment encroaching from all sides, exudates and hemorrhages.

May 7, 1918, both detachments appeared smaller with very numerous hemorrhages and exudates and blurred nerves; exudates at macula less marked. June 10, 1918, V.:

O.D. —1.00 ⊃ —1.00 cyl. ax. 180 = 2/200.

O.S. —1.00 ⊃ —1.00 cyl. ax. 180 = 20/200. No detachment could be made out, but neuro-retinitis still existed with some laying down of connective tissue, especially along vessels. July 22, 1918, V.:

O.D. —1.00 ⊃ —1.00 cyl. ax. 180 = 20/40—.

O.S. —1.00 ⊃ —1.00 cyl. ax. 180 = 20/100. Nerve heads still indistinct, but with good color, few exudates and hemorrhages which are absorbing. Connective tissues being laid

down about vessels still more prominent. Fields showed concentric contraction which would rather suggest beginning atrophy of optic nerves, altho their color was still good.

September 18, 1918, nerves had good color. All active conditions subsiding. Vision, R. = 20/70, L. = 20/30—.

still born child delivered on June 26.

June 27, 1918, eye examination. Pupils dilated and ophthalmoscope reveals almost complete detachment of each retina. Right eye shows (Fig. 3) a very large detachment extending horizontally across the lower part of fundus and upward to within about

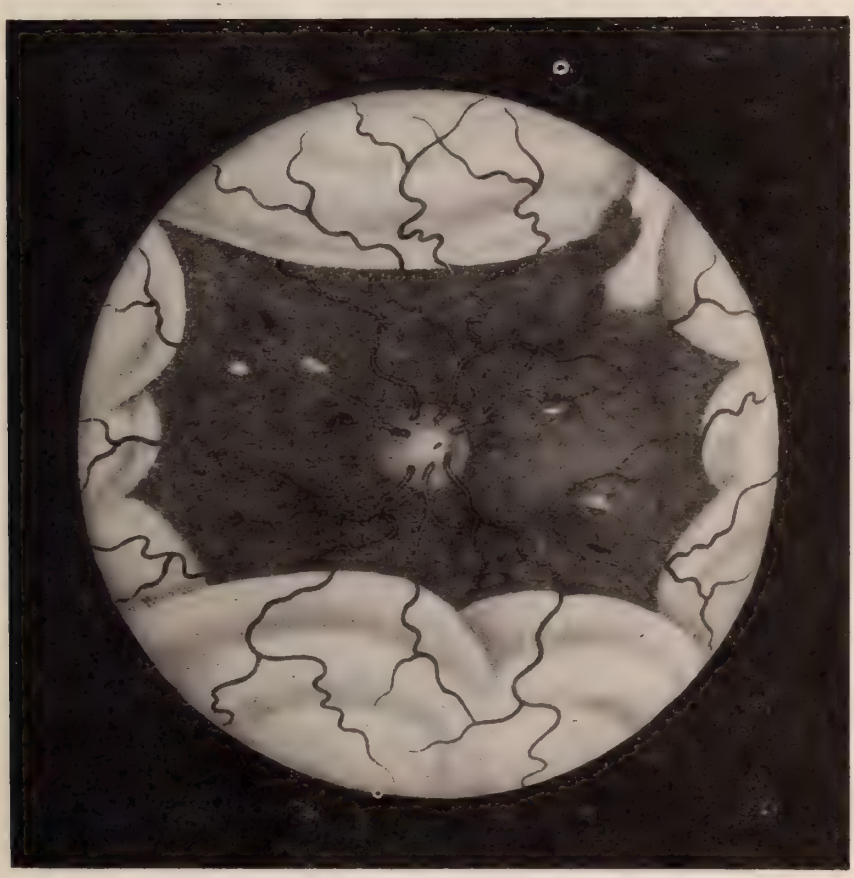

Fig. 4. Case III. Left eye resembling the right eye but with larger hemorrhages.

Case III.—E. B., (colored), age 38. Entered hospital June 25, 1918.

Family and past history, negative.

Present history: This is a fourth pregnancy and everything appeared normal until two weeks ago, when vision began to fail. Patient walked into hospital and was put to bed. Blood pressure 270/160; urine showed albumin with hyalin and granular casts. Membranes were ruptured and

one disc diameter of nerve head. There is another detachment above, which is not quite so large and these detachments are connected at each end by several smaller detachments, giving one the impression of looking down a cylinder. There is blurring of nerve outlines, with general edema of the retina, with few small exudates and hemorrhages. Left eye shows (Fig. 4) practically same condition except that the upper detachment seems to be

larger than the lower, and at the temporal extremity of the upper detachment there is a large exudate bordered by a hemorrhage

July 9, 1918, fundus reflex seen in all parts of fields, nerves still indistinct, considerable twisting of vessels with apparently some fluid under the retina

Fig. 5. Case IV. Right eye. Edema of retina, small detachment, central exudate and hemorrhage near disc.

at the periphery, and numerous exudates about left nerve. Patient was treated by hot packs, salt solution, etc. Patient became delirious and violent and was taken home by relatives against physician's advice on July 9, 1918.

July 24, 1918, patient examined at home; mental condition good, claims to see *well*. Examination shows neuroretinitis, but no detachment. July 31, 1918, at office, V. = O.D. 2/200, O.S. 20/100, no detachment visible. August 8, 1918, fields practically normal for form and no detachment can be seen, with undilated pupils. Both pupils dilated; still a well-marked neuroretinitis, but swelling of nerve heads subsiding and no detachment visible. V. = O.D. 20/200, O.S. 20/100.

Case IV.—R. M. Aet. 26. November 15, 1918.

Family, personal and marital history unimportant.

Present history: Patient walked into hospital and examination showed nearly full term pregnancy with marked edema of face and abdomen. Patient complains of headache, dizziness and dark spots before eyes. Pa-

tient was restless and anxious; B. P. 170/92. Eliminative treatment inaugurated.

November 16, 1918, urine report shows albumin with hyalin casts. Patient very uncomfortable with nausea and vomiting. B. P. 195/120. Hot packs and eliminative treatment continued.

Chart notes in reference to eyes were as follows: 11-19-18, 4 p. m.: Both pupils normal in size. Fundi examined by direct method with undilated pupils gave impression at first that there was no lesion outside of slight edema of retina; but in looking in periphery of fundus in O.D. was discovered a whitish reflex which upon closer scrutiny proved to be a detachment. See Fig. 5.

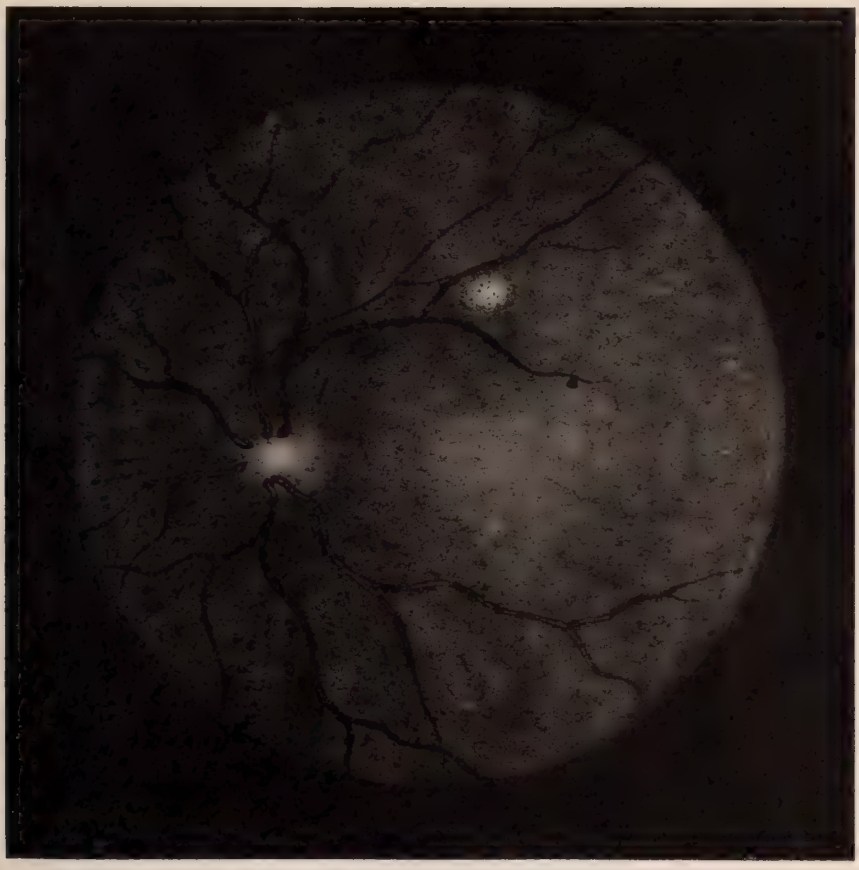

Fig. 6. Case IV. Left eye. Retinal edema, exudate and minute hemorrhages.

November 17, 1918, B. P. 170/120. Labor pains commenced at 4 p. m.

November 18, 1918, pains continued thru day with pronounced headache and nervousness, and blurring before eyes.

November 19, 1918, patient showed signs of exhaustion and child delivered instrumentally at 11 a. m. Patient was continued on eliminative treatment with clearing up of edema and albumin, being discharged in fair condition on December 2, 1918.

Pupils were then dilated with one drop of homatropin. Right eye shows practically entire obliteration of nerve outlines with general edema of retina. Just below and to nasal side was a small diffuse hemorrhage, while just above macula there was an area of infiltration through which the retinal reflex could be seen in places.

Retinal edema became more marked as one followed the superior temporal

vessels outward until some little distance beyond the macula, where was found a good sized detachment of the retina, the lower portion extending to the temporal equator having most fluid beneath the retina while the upper fold faded away to normal retinal level.

Left eye showed physiologic cup filled in and nerve borders indistinct, udates near macula. Upper outer quadrant shows no detachment of retina, but numerous small pigmented areas; no hemorrhage found. O.S. shows blurring of nerve, with thin exudate near macula, hemorrhages absorbing. Fields taken by Peter's campimeter show normal outlines.

12-1-18: Pupils dilated, no ophthal-

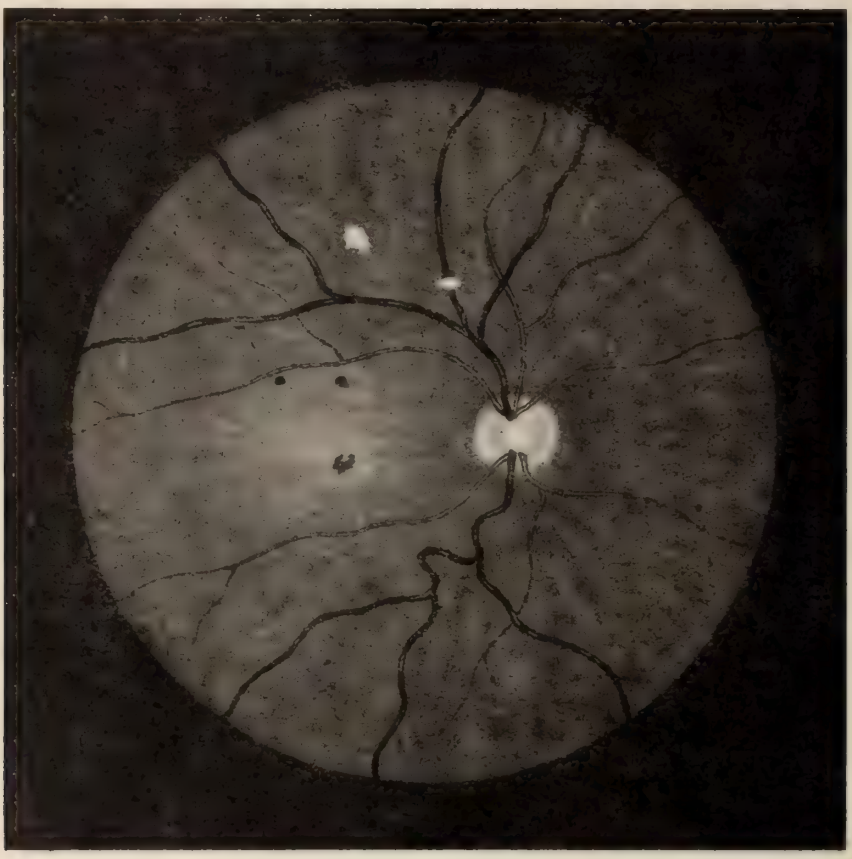

Fig. 7. Case V. Right eye. Retinal exudates and hemorrhages.

general retinal edema especially about nerve and macular region. Just above macula in close proximity to a vessel there is a thin exudate, while just above and to the temporal side are seen two small hemorrhages, the one nearest the nerve being a minute linear one, and the more distal one being several fine points. See Fig. 6.

11-28-18: Fundi examination with undilated pupils shows, O.D. blurring of optic nerve with two areas of thin exmoscopic change in findings from November 28, 1918.

Case V.—Mrs. F., (white), age 40. Entered the hospital February 8, 1919.

Family history negative. Marital history, eleven children without previous trouble. Present history, entered the hospital with history that eyes had been getting blurred for five days, which condition had been growing worse.

Examination upon entrance showed

patient eight months pregnant, blood pressure 205/110 and presence of marked albumin, with red blood cells and hyalin casts in urine.

Eye examination 4 p. m. on February 8, with dilated pupils and direct examination showed blurring of right nerve head, vessels large and tortuous, with marked edema of the retina, espe-

rhages seen. About two nerve heads below disc, retina was detached, with typical white appearance, more on the order of a very large wrinkle than complete detachment, as slight pinkish reflex could be made out in the periphery. (See Fig. 8).

February 9, 1919. Eye examination, just after delivery of a male child,

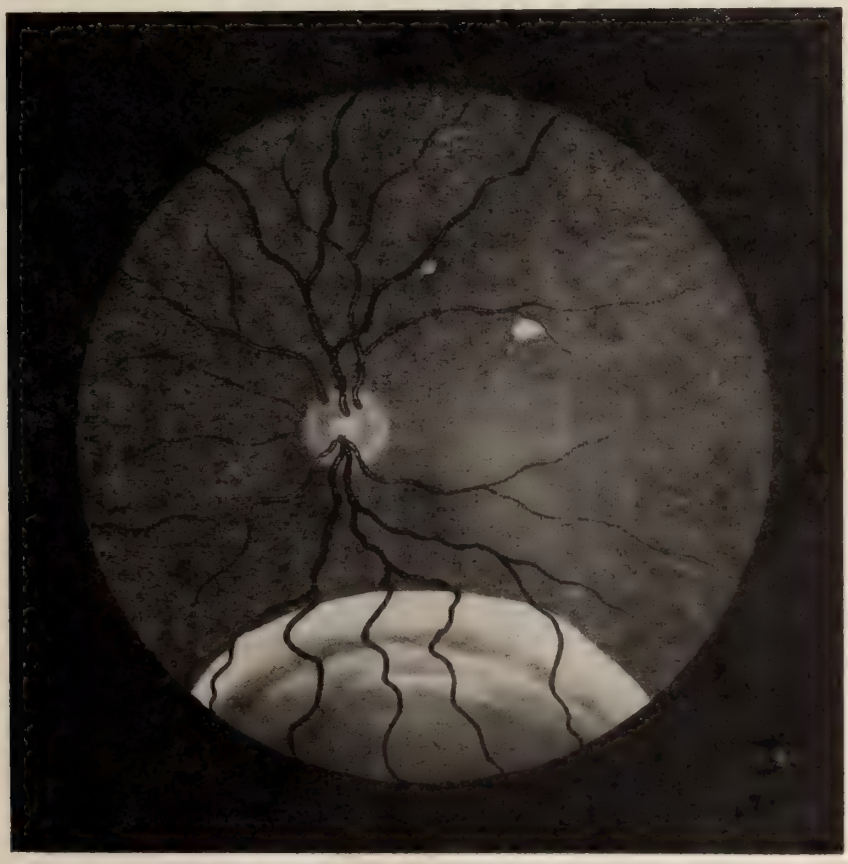

Fig. 8. Case V. Left eye. Detachment below, exudates above.

cially about macula, and several exudates and hemorrhages; the exudates being most marked along the superior temporal vessels, while the hemorrhages were near macula and below. Lower temporal vessels seemingly raised and more tortuous than others. (See Fig. 7). Left eye showed same condition about nerve, with tortuosity of vessels and edema of the retina. There was rather a large exudate just above macula near vessel; no hemor-

weight 5¾ lbs., no change could be noted. February 10, 1919, fundus examination showed no change in the right eye, but left eye showed an almost complete return of the retina to its bed, so much so that we were unable to demonstrate any detachment. Patient continued to show a neuroretinitis, with hemorrhages and exudates in right eye and exudates in left, until March 4, when she insisted upon leaving the hospital. Blood pressure was

then systolic 145, with a trace of albumin in the urine.

Case VI.—L. H., (white), age 33. Hopkins Maternity Ward.

History: Has had eight children, all living. Four weeks ago began to have swelling of limbs and was admitted to maternity ward on March 15, 1919, with edematous condition very marked. B. P. 205/110. Urine showed albumin and casts. Patient was delivered March 16, 1919, and this was followed by a couple of convulsions. Patient states she has had poor vision for two or three weeks.

Eye examination on March 19, at 5 p. m. showed pronounced blurring of outlines of right nerve, with retinal edema, vessels large and tortuous; as superior temporal vessels were followed outward there was noted increased tortuosity with definite elevation of retina measuring between 6 and 7 diopters. Pinkish reflex was present thruout this region, but definite wrinkling of retina was seen, several small exudates were noted in the edematous area about nerve and macula and one small hemorrhage near lower inferior nasal vessel. (See Fig. 9).

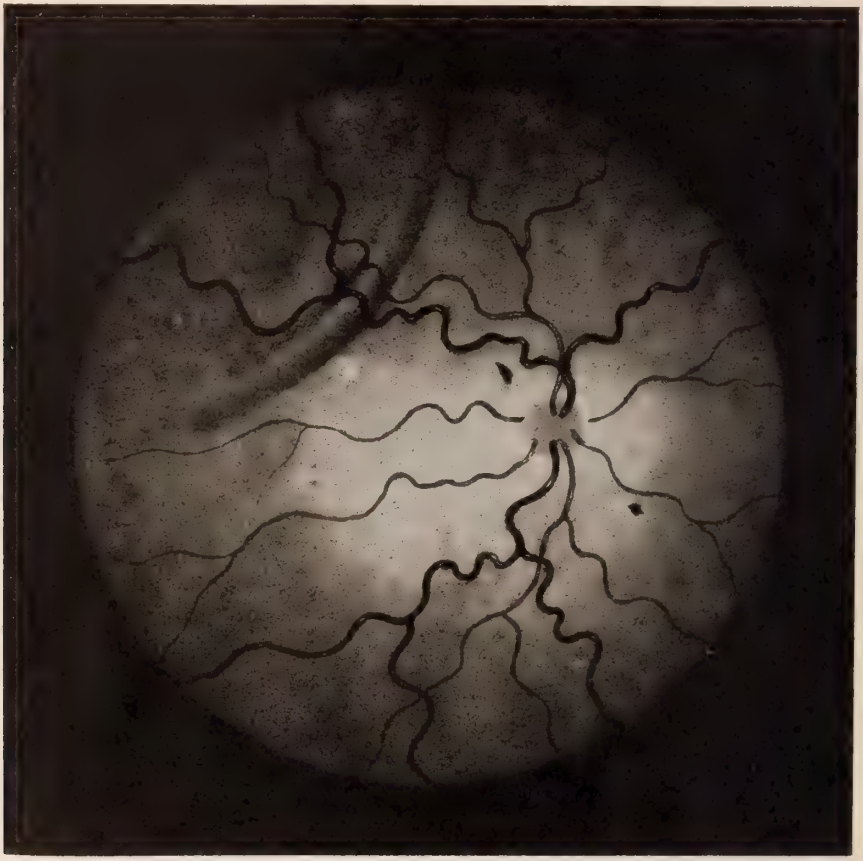

Fig. 9. Case VI. Right eye. Retinal edema, enlarged vessels, and fold of detachment up and out.

Left fundus showed same general condition as right, in the blurring of nerve head, retinal edema and small exudates and hemorrhages and tortuosity of vessels, but these were more pronounced just below and to the temporal side of the fundus, where wrinkling of the inner coat was found and where there was approximately the same elevation as in O. D., from 6 to 7 dameters. (See Fig. 10)

March 20, 1919, 3 p. m.: No change in fundi, with possible exception that elevation in O.D. may be less, patient says she sees much better.

March 22, 1919, no elevation of retina in either eye but neuroretinitis still present. Patient states she can see much better.

ment in each eye, and Batten[10] double detachment in a boy having nephritis.

While one can easily see how in any case of inflammation of the inner coats of the eye associated with edema, one could most easily have this transudation poured out under the retina thus producing a detachment, its infre-

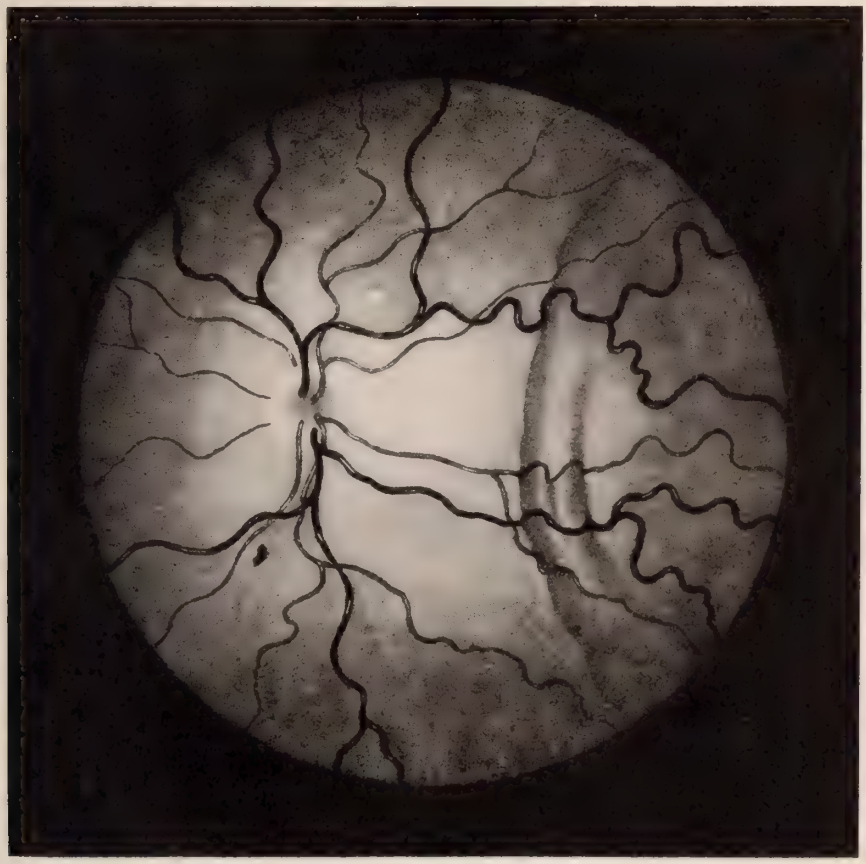

Fig. 10. Case VI. Left eye. Fold of detached retina outward.

April 8, 1919, both fundi show some neuritis, with edema of retina, exudates and hemorrhages.

REMARKS.

It is claimed by some obstetricians, that cases of toxemia or eclampsia which show eye changes, are always secondary to a kidney lesion.

To be sure detached retinas have been reported in cases of pure nephritis, as Jones[9] cites the case of a man having nephritis with double detach-

quency of record in this class of cases is not so easily explained. Many cases of eclampsia show edema of the retina extending from margins of nerve out towards the periphery, without either hemorrhages or exudates. These have been seen with increasing frequency since the introduction of the electric ophthalmoscope and using the direct method of ophthalmoscopy, especially so in those toxemia cases where unconsciousness of patient makes it often exceedingly difficult to make a thoro examination.

Some are now claiming that the unconsciousness is due to cerebral edema, and one can readily see how an edema of the retina starting most frequently with a slight blurring of the optic nerve and extending peripherally could be associated with cerebral edema, and it requires only to carry this pathologic phase one or two steps further to conceive this accumulation in such quantities as to cause separation of the retina from its bed, taking place most frequently in the lower part of fundus first, and then if the condition is not arrested continuing the separation around the entire circumference. When this stage arrives it would be logical to expect that both serum and blood would find their way outside of the vessels and lymphatics, producing exudates and hemorrhages. So much for our hypothesis, now how is it borne out by facts in our cases under observation? In the first case at the first examination, the patient was in profound stupor but the pupils were dilated and both fundi examined by direct method with result as described. Two days later imagine our surprise in finding such a change with double detachment in the right eye and a very large single one below in the left.

Baehr[11] asserts that both coma and convulsions are usually if not always due to cerebral edema either general or localized, and whether this occurs as a result of trauma or from influence of toxins the end results are similar. One is struck by the similarity of fundal pictures as seen in most cases of toxemia of pregnancy with its slightly blurred nerve head and retinal edema and those cases of fractured skull where the eye findings are usually of like degree in blurring of nerve head and edema of retina.

Wilson[12] and Snyder[13] report cases of eclampsia that ceased having convulsions as soon as lumbar puncture was performed, while Zangemeister[14] devotes fifty pages to arguments sustaining the contention that the clinical symptoms (convulsions) are due to intracranial edema.

The mechanism of detachment of the retina as contended by Leber[15] and Nordenson, a fibrillary change in the vitreous, does not seem in these cases to be at all apropos, but it seems more on the order of Raehlman's[16] theory of diffusion.

The first case will not bear out the contention that ophthalmoscopic changes never occur in eclampsia for a case having sixteen typical convulsions would certainly be classified as eclampsia; nor would any of these cases substantiate the theory of excessive congestion except the possibility of case IV. as cases II. and V. occurred before parturition and cases I., III. and VI. were not difficult.

Diagnosis: While the condition as it existed in these cases was very definite and if seen could not have been mistaken by even a novice, I am of the decided opinion that many more cases of detachment occur in eclampsia than are reported and that these occur far in the periphery and are frequently overlooked. Another point which certainly should be kept in mind is a rather frequent examination of these cases, and always with a widely dilated pupil. This is strikingly illustrated in cases I. and V., as the initial examination in case I. was not startling, but a few days later the appearance was far from reassuring and in case V. if examination had been deferred, as frequently happens, no detachment could have been found. Then again let me plead for a very careful paistaking examination, as cases I. and III. were very difficult of examination with the ophthalmoscope, and as the fundi were studied only after some effort; and case IV. was only discovered after careful searching of the periphery. One must also keep in mind the flat detachments as seen in case VI., where definite elevation and wrinkling were found but where the fundus reflex is not lost. It is quite probable that this case had typical detachments and was in the receding stage when first examined.

Prognosis: Altho the appearance is disheartening, and one is likely to give a very grave prognosis as one becomes accustomed to do in idiopathic detachments, here the prognosis de-

pends not so much upon the amount of detachment, but upon the accompanying neuroretinitis as well as upon the length of time that this has existed. The prognosis in reference to the detachment is exceptionally good as evidenced in this report, and also of cases cited, but as to ultimate vision it must of necessity be guarded as the neuroretinitis is often followed by marked permanent impairment of functioning retina.

Treatment: Altho eliminating treatment is essential after the condition is well marked, the most important treatment is prophylactic. In this age of modern medicine when blurring of vision occurs in any stage of pregnancy, and especially in the latter months, there should be a most careful and painstaking fundal examination, and in cases where there is found neuroretinitis, either with or without detachments, certainly from an ophthalmologic standpoint, premature delivery is justified.

While none of this series was treated by spinal puncture, I feel certain that repeated spinal puncture is a procedure that is at least worthy of trial.

As to local treatment I am inclined to the belief that negative is as valuable as positive treatment, and that nearly the entire result depends upon active elimination as outlined by the attending obstetrician. Case I. had active local treatment in the form of pressure, bandage, recumbent position, etc., but one could see no more marked improvement than in cases II., III., IV., V. and VI., where little or no local treatment was used. To be sure cases II., III. and V. did not have such good end results, but that occurred as a result of the neuroretinitis, which was of longer duration with more extensive scarring of retinal and nerve tissue, while case IV. I am sure had good end results, altho I was never able to get her to return to check up the vision, and case VI. is still in the hospital.

Summary: Retinal detachment in eclampsia is, according to most authors, a very rare condition and conspicuous by a paucity of literature. Six such cases have been under our observation since December, 1917, varying in extent from small to almost complete detachment of the retina. In contradistinction to so-called iodiopathic detachments, these have all subsided and become reattached with normal fields of vision.

They may be antepartum or postpartum, and may clear up in a few hours, and are frequently far forward in the periphery and found only after some searching. They are probably present much more frequently than heretofore recorded, and the prognosis is good so far as the detachment is concerned.

CONJUNCTIVITIS DUE TO FOOD ANAPHYLAXIS.

FRANK A. CONLON, M. D.

LAWRENCE, MASS.

This paper calls attention to an unusual condition of extreme interest and some practical importance, and reports three cases.

It has long been known that certain foods, when eaten by individuals peculiarly sensitive or anaphylactic to these foods, develop certain symptoms or ill effects. Among the better known disturbances are urticaria, eczema, vasomotor rhinitis, angioneurotic edema, and bronchial asthma.

I shall produce evidence to show that conjunctivitis unaccompanied by any other manifestation may also be produced by the proteins of commonly used foods which up-to-date have not been recognized as causes of this disease. My attention was called to this possibility by stubborn inflammations of the conjunctiva recurring in the same patient at or about the same time year after year. Most of these cases had been treated for a considerable period of time before I saw them but had never had any treatment that permanently relieved or shortened the attacks. For a time the determination of the offending food was by either guess work or elimination. When the food happened to be a fruit or a vegetable which was eaten only at certain times of the year the diagnosis was comparatively easy. For a number of years I have seen cases in which I considered certain foods as possible causes of this recurring conjunctivitis, but owing to lack of coöperation and careful observation on the part of the patients I was not definitely convinced that such was the fact.

In the summer of 1915 I was very fortunate in having for a patient a young man who was not only intelligent and observing but who was willing to carry out any and all suggestions I proposed. For five or six years he had suffered from "sore eyes," which generally began in May and continued off and on till late in the fall. When I first saw him his lids appeared somewhat reddened and swollen, with a suggestion of a slight ptosis such as one sees in trachoma. The bulbar conjunctiva was markedly hyperemic, with a more moderate hyperemia of the palpebral conjunctiva. During the following two years he definitely proved to me and himself that his conjunctivitis was due to eating either strawberries or tomatoes. The patient was convinced long before I was. He would report in the afternoon with a conjunctiva that appeared normal, then eat freely of tomatoes or strawberries and return the following day with the usual "sore eyes."

During the time he has been under observation he has never had his "red eyes" except after eating one of the offending foods, nor has the eating of these foods ever failed to cause a hyperemia of the conjunctiva. Last fall this patient reported again, saying that some new food was causing a recurrence of his old trouble. The protein skin tests showed no new sensitization. I did find, however, that he had indulged in a catsup which contained tomatoes. We then found that this, when eaten on baked beans, always brought on a marked conjunctival hyperemia.

The protein skin test is the one used by Walker[1] in his investigations of the cause of bronchial asthma. The proteins used are prepared by Wodehouse[2], who in 1916 described the preparation and method of manufacture. The skin test is made as follows:

"A number of small cuts, each about an eighth of an inch long, are made on the flexor surface of the forearm. These cuts are made with a sharp scalpel, but are not deep enough to draw blood, although they do penetrate the skin. On each cut is placed a protein and to it is added a drop of tenth normal sodium hydroxid solution to dissolve the protein and permit

of its rapid absorption. At the end of a half hour the proteins are washed off and the reactions are noted, always comparing the inoculated cuts with normal controls on which no protein was placed. A positive reaction consists of a raised white elevation or urticarial wheal surrounding the cut. The smallest reaction called positive must measure 0.5 cm. in diameter."

The use of the skin test makes the diagnosis comparatively easy and cases are now found that ordinarily would escape detection. The majority of these cases are of moderate conjunctival injection and generally the patient's only complaint is as to the appearance of his eyes.

These patients may, however, present very annoying eye symptoms, as the following case will show.

A. B. R., 56 years, male, merchant. For the past four or five years he has been unable to read for more than five minutes at a time without, as he expresses it, "a feeling of sand in his eyes, the lids feel constantly as they do when one is very sleepy." He has rather frequent, sudden attacks of lacrimation, which come on without any known cause and stop as suddenly as they started. He says that he has had a perfectly miserable time of it for the past couple of years, with practically constant eye discomfort; so he became an "early to bed and late to rise" sort of a fellow, as the only time he was at all comfortable was when his eyes were closed. His glasses had been changed a number of times, tinted lenses had been ordered and worn, drops of various kinds and colors had been prescribed and used without any benefit whatsoever. The eye lids were slightly swollen and congested and there was a general enlargement of the conjunctival blood vessels which was more marked on the bulbar conjunctiva. Nothing found in nose or throat. General condition good. No bad habits, did not smoke or drink, and I could not find any change necessary in his glasses. The elimination of eggs from his diet was shortly followed by a total disappearance of his annoying symptoms. For the past two years he has been able to use his eyes as he wished, and he informs me that life is once more worth living. One control test followed by a return of his symptoms was all I could persuade this patient to make.

On a recent skin test with some thirty odd proteins this patient reacted to egg alone. This case is of additional interest in that as a child he suffered for eight or nine years from asthma and then later in life from hay fever. It may be that as a child he had a bronchial asthma from some food protein, outgrew this sensitization, and then became sensitized to rag weed or timothy pollen, to which in time he also became antianaphylactic, only to develop a few years ago a sensitization to egg protein.

The skin test should be made at the time the patient is suffering from the conjunctivitis, as in some people the anaphylactic reaction disappears after the patient abstains from the offending food any length of time, to reappear again on eating it.

In other cases one finds a positive reaction where the patient has eaten the offending food but once or twice during his whole life.

Talbot[3] has found infants who have never tasted egg, but who gave a positive skin reaction to egg.

In a number of cases the tendency to protein sensitization seems to be hereditary, as frequently the patient will volunteer the information that other members of his immediate family are subject to annoying and, at times, alarming symptoms after eating a special food.

People are frequently found who react to two or more of a group of closely related proteins, while in others the reaction is to one specified protein, as the following case illustrates.

Case 3.—A. H., 28 years. Male. For the past five years this man has suffered from an inflammation of the right upper lid which always occurred during or immediately following his summer vacation. While away he spent most of his time fishing for flounders, which he ate two or three times a day. During the remainder of the year he

ate very little fish and never any flounders. Not being able to obtain flounder protein, at the suggestion of Wodehouse I tried sole protein, as sole is a sort of first cousin to flounder, but obtained no results. Thinking that possibly too long a time had elapsed since the ingestion of this fish, two months later I requested the patient to eat flounder a few times so that I could again try the skin test. On the day following a two-meal test the lid inflammation recurred, but the sole protein test remained negative. I now prepared a home-made protein, and with this obtained a positive reaction.

In the absence of uncorrected ametropia, all recurring low grade inflammation of the conjunctiva which the patient calls "frequent attacks of red eyes," should be considered as possibly due to food anaphylaxis. This is especially true when the attacks appear the same month year after year. After obtaining a positive skin test the proof as to this food being the cause of the conjunctivitis is very readily obtained by the patient.

I believe that a number of diseases whose etiology is now grouped under the indefinite head of autointoxication will be found on closer examination to be anaphylactic phenomena.

In conclusion I will add that I also believe that the study of food protein anaphylaxis and bacterial protein anaphylaxis will explain the etiology of a number of eye diseases, especially keratitis and low grade inflammation of the uveal tract, and open up vast and fruitful fields for investigation.

OCULAR LESIONS CONSECUTIVE TO INJECTIONS OF ANTITYPHOID VACCINE, KERATITIS HERPETICA FEBRILIS.

R. Pacheco Luna, M. D.

GUATEMALA, CENTRAL AMERICA.

This paper reports a case of ocular lesions following antityphoid vaccination, and reviews the previously reported cases, and the conclusions that have been drawn from them.

The scientific periodicals have been publishing for one year and a half a series of very interesting articles about the ocular lesions resulting in a small number of persons inoculated with antityphoid vaccine. We add a case in which were observed some points which have been previously noted and published.

Our patient, a German of 52, a bookkeeper by occupation, has resided in Guatemala since his 20th year. He has no pathologic record nor antecedents of any importance. He acclimated himself easily to the tropics, and has always lived in the city (1,500 meters altitude). Three years ago, being on a vacation in New Orleans, he had a herpetic keratitis, following catarrh of the upper air passages, for which he had consulted us on his return; and we could retrospectively trace the picture of the disease by dimness of vision, photophobia, lacrimation, conjunctival and ciliary injection, anesthesia, and dendriform ulceration of the cornea, miosis and hypotension, without pain or elevation of temperature, and no lesions of the face. A general examination was made, but the keratitis could not be attributed to any other cause than the catarrh of the upper air passages which preceded it. Under proper treatment it yielded in due time, leaving a thin, superficial opacity on the anterior part of the cor-

nea, which disappeared completely. Final vision result = 9/10.

During the three years that have elapsed from that time, the eye had been quiet until the 15th of May of the current year. On the evening of the 13th he received a third dose of 1 cc. of Mulford's "Typho-Bacterin Mixed," which contains per cc.:

1,000 millions of dead typhoid bacilli
500 millions of dead paratyphoid A. bacilli
500 millions of dead paratyphoid B. bacilli.

This injection was given on Monday at 6 P. M., and from midnight and all Tuesday he had a fever (39,6°C.), headaches, boneaches and general malaise. In the evening the pain decreased, the temperature fell and a cluster of nasolabial herpes appeared on the right half of the face. On Wednesday, he awakened with an inflamed, red, right eye, photophobia, constant lacrimation and blurred vision.

He consulted a physician immediately, who prescribed a solution of nitrat of silver; but remembering having previously had something similar, in which we had assisted him, he consulted us on Sunday, the 19th.

On that date the picture was the following: Right eye; diminution of visual acuity, photophobia, lacrimation, constant sensation of a foreign body, strong conjunctival and ciliary injection, two central, branching, superficial ulcerations of the cornea. Pupil sluggish and contracted, anesthesia of the cornea. Tension: diminished. In the nasolabial region of the right side I found dried herpetic particles. The teeth, gums, tonsils, nasal fossae and sinuses were healthy, and no area of focal infections was found. The point of injection did not present the least sign of infection.

We thought immediately of a herpes febrilis of the cornea, consecutive to an injection of polyvalent antityphoid vaccine, developed in a subject whose examination did not reveal other causes, but who had among antecedents a previous appearance of catarrhal herpes on the cornea, and to this anteceding lesion we attribute a great importance on which we will report later.

Morax[1] was the first who gave the alarm, publishing a case in whom, after a febrile access caused by an injection of T. A. B., a keratitis herpetica developed, which was of slight importance, since the patient recovered vision completely.

Gloagen,[2] chief of the ophthalmologic clinic of the Maritime Hospital of Cherbourg, records three other cases of keratitis herpetica. In the first case the third injection produced fever of 40° C., headaches, boneaches, which induced the physician to make a lumbar puncture on the following day. That same day an intense nasolabial herpes broke out. Three days later there appeared in the right eye a classic herpetic keratitis and the fluorescein showed the fine ramifications. The affection was cured in eighteen days, but a thin opacity of the cornea persisted which reduced the vision to 0.6.

In the second case the fourth injection was followed by general malaise, headaches, fever (40° C.). After the following day, nasolabial herpes appeared. Three days later, besides a dense palpebral herpes of the upper lid, a typical herpetic keratitis which affected almost all of the cornea, was observed. Cure in 25 days, but an opacity persisted which reduced the vision to 0.1.

These observations relate to herpes febrilis of the cornea. It is very difficult to judge them if they are not submitted to an impartial analysis, owing to the intimate relation which seems to exist between the cause and the effect. An incorrect interpretation would be extremely detrimental to a new prophylactic method which is expected to give incalculable service to humanity. We shall endeavor to interpret these observations for which we need to note other ocular affections which have occurred immediately after vaccination.

The febrile form is one variety of herpes of the cornea. It shows itself in the infectious diseases, accompanied by vesicular eruptions of the skin of

the face and of certain mucous membranes; and is considered a toxic neuritis of the trigeminus, the herpetic keratitis being a neuritis of the terminal filaments of the ciliary nerves.

All the observations are identical. One of the inoculations is followed by a febrile access, after which herpes appeared upon the skin of the face and the mucosa, followed by appearance of herpes on the cornea. The injection of T. A. B. is the cause of the fever, and the herpetic appearance. Let us note immediately that this latter is rather exceptional, considering the great number of vaccinations which are made.

We might suppose that the cause of the fever is a microbe, which has developed in a badly prepared or poorly preserved vaccine. We also presume that the microbes can find entrance into the organism by a faulty technic. One can imagine that a febrile access acts by reviving a latent infectious focus, preexisting in some part of the body. However, the microbes secrete toxins which affect certain nerves; or one could finally explain the process, by the action of a proteid substance which developed in the vaccine, and has the property of producing fever and irritation of the trigeminus.

The accepted opinion is that the antityphoid vaccine by itself can be the direct cause of the herpes of the cornea, it not being possible to find another cause. The observation that we present is very interesting because it treats of recurrence and our patient is therefore a subject predisposed to the nervous lesion, which presented itself before in an identical form, without the vaccine having to figure in the etiology of the process. The first time, a catarrh of the upper air passages preceded the lesions of the eye; and now it appears after a reaction of T. A. B., which brings us to the following conclusions: It has been supposed that the febrile herpes of the cornea directly depends upon the antityphoid vaccine; but our observation modifies this opinion because in our patient a predisposition existed.

Prof. de Lapersonne[3] published a case, a résumé of which we reproduce herewith. A soldier, after the second or third injection had multiple abscesses and infectious broncho-pneumonia; and in the course of this pulmonary complication, presented a unilateral metastatic ophthalmia. After such grave general complications he recovered with an atrophied and painful eye, which it was necessary to enucleate some days later. De Lapersonne thinks that the microbes of the infection, introduced into the organism with the vaccine, were the cause of that pyemia; but not the vaccine which does not contain infectious germs.

He considered this case extremely rare, but he thinks it should be known, so that in the future one may avoid similar cases by strictly following the rules of asepsis; and he advises that the patients be rigorously examined before vaccinating them, because latent infectious foci can be revived; and the visual organs must be especially examined by an oculist. Besides an infection, a recurrence of an iridocyclitis can happen. Avoid them in people who are predisposed thru a persisting pathologic state. In this manner one can conceive that in the luetic, rheumatic, tubercular, or in anyone who may have had a generalized gonococcic infection, etc., ocular lesions can appear when a violent reaction happens.

Calhoun[4] published two observations in an article entitled "Anti-Typhoid Inoculations and Ocular Lesions." The first observation was in a lawyer with a slightly positive Neisser reaction, who presented a typical iritis the day following an injection of T. A. B. The other case was in a luetic with a + + + positive Wassermann. Three days after the third injection the vision blurred and the examination showed several deposits on the posterior wall of the cornea, opacity of the vitreous, and two patches of acute choroiditis. Salvarsan, mercury and iodides made the lesions disappear.

Prélat,[5] who published a case similar to the second of Calhoun, thinks it very questionable if the vaccine has a predisposing action. There are reasons why, in such a patient a plastic luetic

iridocyclitis may develop, without it being necessary to resort to the antityphoid injection to explain genesis. Indeed, the luetic origin of double iridocyclitis not only seems to be possible, but certain, the antecedents, the clinical signs, the Wassermann, the favorable result that the treatment gave are positive proofs. It nullifies the hypothesis of direct action of the vaccine, but suggests that this may have played a coöperative part. On the other hand I find it very fair to bring to notice that, with the number of vaccinations which are given, it must be possible to meet one with some recurrences.

From his observations he finally deduces the following conclusions:

(1) The antityphoid vaccine in the luetic subject safe from any complications, does not seem to have any danger. If in these conditions some complications arise, it is not possible to make the injections responsible for the lesions. On the contrary, he considers it prudent, as de Lapersonne advises, to abstain from that practice in luetic and tubercular subjects, etc., who may have had lesions of the uveal tract, because they can be revived under the influence of the vaccine.

(2) Owing to the medico-legal consequences that might arise, in similar cases, the accidents that present themselves after the injections of T. A. B. must not be attributed to the vaccine until after a complete and minute examination of the patient; and it is not possible to accept this etiology without great circumspection and after a satisfactory verification. The observation of that patient is a proof of the necessity to judge such facts with extreme prudence.

The observations of Etienne Ginestous[6] belong to a circle of simple and tedious coincidences, because in the traumatism of an ocular globe, even in a very grave case like that which is the object of the first observation, it is usual to observe in practice momentary improvements, followed by rapid reactions which threaten the vision, or even produce amaurosis. This should not surprise ..., nor do we find this case exceptional. It concerns a shoemaker 19 years of age who, while playing, received a heavy blow on the right eye and lost the vision instantly. But on the following days he presented certain improvements even to the point of recovering one-fourth of his vision. On a day following an injection of T. A. B. he lost the sight again and he did not recover. Traumatic neuritis developed, nearing atrophy, an ordinary process in which it is not possible to account for direct influence of the vaccine.

The second case of the same author concerns a myope, with posterior staphyloma and chorioretinitis, vision with a $-5 = 2/3$. After a third injection, which caused fever and diarrhea, he noticed that his vision diminished to 1/6, after correction. We remember that the lesions of the retina of the myope can progress and the visual acuity diminish, even after the defect was corrected; and that at a certain moment, without the apparent determinating cause, a rapid diminution of vision occur. One must consider the immense number of myopes inoculated with T. A. B., and none of them complaining of poor vision after vaccination, and we also note that many myopes, without receiving any inoculations, suffer diminution of vision.

Other troubles have been observed, such as lesions of the retina (Morax), ocular motor nerve paralysis (Morax and Bourdier), whose etiology is most questionable, as it concerns luetics or patients whose luetic records have not been investigated. Morax himself admits that it is a question of coincidences, such as happens in the two observations of Ginestous. In résumé: It is a question of late consequences, of known processes which in their evolution do not diverge at all from the usual, and therefore do not seem influenced at all by the antityphoid vaccine.

So far there have not been published any cases of retrobulbar neuritis. De Lapersonne would explain them by a meningeal reaction of the sheath of the optic nerve. Of the same nature would be the lesions of the optic tracts and also those of the motor nerves.

He advises extreme prudence and really admits the action of the vaccine only in those cases in which the different clinical and laboratory examinations, and very particularly the reaction of Wassermann, have been negative.

It is necessary to differentiate the glaucomas. Is it a question of glaucoma secondary to old irido-cyclitis, with pupillar occlusion? Nothing is more easy than to think of an acute attack developed during a violent reaction.

The explanation of the acute and subacute glaucoma is much more embarrassing; and it would be really difficult in this case to deny the influence of the vaccine or to explain the process of a chronic glaucoma whose pathology is far from being clear, the manner in which the vaccine could aggravate it is not evident, above all when the aggravation is late, more than one month, and a febrile access did not follow the injections.

So far our knowledge of ocular lesions consecutive to injections of antityphoid vaccine is limited; but as conclusions one could establish the following propositions, which, with some exceptions, are the views of the majority of the authors referred to.

1. There exists no ocular lesion depending directly and exclusively upon the antityphoid vaccine.

2. Herpes febrilis of the cornea is the ocular lesion which is admittedly dependent upon antityphoid vaccine; but in certain cases, as in our observation, it dealt with a recurrence, and one must admit a predisposition.

3. In a like manner, the cases of iridocyclitis which have a constitutional defect must be considered. A reaction of the vaccine can bring on secondary glaucoma depending upon iridocyclitis.

4. Pyemia, whose cause is a fault of asepsis in the technic, can produce grave complications of metastatic purulent iridocyclitis.

5. Certain lesions of the optic nerves, the optic tracts and certain ocular paralyses, of which, so far, no observations have been published, could be explained by meningeal reaction.

6. An acute primary glaucoma can develop during the reaction of the vaccine. It is not possible scientifically to express in what manner a chronic glaucoma would be aggravated.

7. To admit the action of the vaccine, it is necessary that the ocular manifestations should present themselves during the febrile reaction or immediately after.

8. In certain cases it is not possible to attribute to the vaccine any action at all, it is simply a question of annoying coincidences.

9. It is not prudent to vaccinate luetic, tubercular, and rheumatic subjects, etc., who may have previously had lesions of the uveal tract.

10. There is no reason to deprive those subjects of the benefits of the vaccine who had no former lesions of the uveal tract; who are exempt, therefore, from all former ocular affections.

11. The patient must be submitted to a previous medical examination, and the examination of the eyes entrusted to an oculist.

12. Before judging on a medico-legal matter, due to the vaccine, it is necessary to use great circumspection and to have a perfect knowledge of all that has been said on the subject.

THE EFFECTS OF FAULTY CRANIO-SPINAL FORM AND ALIGNMENT UPON THE EYES.

LLOYD MILLS, M. D., F. A. C. S.

LOS ANGELES, CALIFORNIA.

Faulty posture of the head and spinal curvature are generally recognized as effects of ocular anomalies. This paper points out the reverse relation may be true, and the ocular symptoms relieved by orthopedic treatment.

Tilting of the head, high-headedness and its converse have long been recognized as products of, or have been found in such constant relation to the various heterophorias and heterotropias, notably the cyclophorias, as to fix the opinion that the cause of the ocular misplacements and torsion, and consequently of the cranial malposition, was primarily a fault of action of the extrinsic ocular muscles and particularly of the obliques.

Spectacular cures of marked torticollis, effected by operating upon these muscles in a few cases, further so emphasized this opinion, that the possibility of faulty cranial posture, as a primary result of marked cranial asymmetry, or secondary to faults of spinal alignment or of actual vertebral lesions, acting to produce ocular torsion and changed corneal curvature thru compensatory overaction of certain groups of extrinsic ocular muscles in their effort to achieve and maintain normal spatial orientation, apparently never were considered.

Prior to the inception of our work in August 1915, ophthalmic and orthopedic literatures were barren of facts dealing with such an association. In fact the ophthalmologist limited his notions of ocular mechanics to the orbit, while the orthopedist rarely went above the seventh cervical vertebra, from which point he usually dropped a plumb line in spinal examinations.

Our interest in this problem arose from having seen projectile wounds of the cervico-dorsal spine with frank ocular symptoms; from a case of acute glaucoma in which the first symptom, acute cutting pain in the cervico-dorsal region, was so agonizing as to mask the ocular lesion, or symptom, temporarily; from observing that obvious and gross skeletal deformity seemed more prevalent among cases of manifest squint than among ordinary eye cases and, finally, from noting that the sub-occipital and nuchal aching which accompanied many of the more marked refractive and muscular faults very often did not yield to the most accurately prescribed lenses or to muscle training, but were often temporarily relieved by cervical massage or manipulation.

A chance discussion of some of these facts with Dr. Charles L. Lowman, a capable orthopedic surgeon, revealed the fact that he had noted improvement or relief of eye symptoms in patients coming to him for such remote static lesions as flat foot, hip disease and, more frequently, cervico-dorsal lesions. "Pulling," "drawing" or "burning" sensations in the neck and back were common complaints among the last class, and were more pronounced during or after sewing, reading, writing, typing or watching moving-pictures, activities which require stabilization of the head, or shoulder-girdle fixation (essential to the use of the hands in any finely coordinated work) or both, as an essential to intense ocular fixation, thus putting strain on all the muscular and ligamentous attachments and structures involved in maintaining head balance and in fixing the shoulder-girdle.

We knew that only about ten per cent of all individuals could be classed, posturally, as belonging to the "ideally normal type." It was estimated that emmetropia and normal muscle balance existed in about an equal per cent of individuals and the parallelism seemed suggestive. Further, lateral and antero-posterior deformities of the spine are very common, anatomic pecu-

liarities are frequent in the cervical region and cranial asymmetry is the rule.

It seemed logical to assume, therefore, that not only could spinal curves and rotations be evolved compensatorily in the mechanics of balancing unequally weighted cranial halves upon the spine, but also that faults of cranial posture, such as tilting and high-headedness, could be the compensatory postural result of spinal bends and torsions due to unilateral leg deformities and faults in pelvic alignment, as well as to original lesions of the spine. We assumed, further, that the eyes could be involved in these skeletal defects; first thru reflex irritation, stretching or pressure upon the cilio-spinal sympathetic center and pathways, a relation to be detailed in a subsequent paper (American Encyclopedia of Ophthalmology, Vol. XV, *Spinal Affections*); and secondly thru compensatory action of the extrinsic ocular muscles producing compensatory heterophorias and heterotropias and presumably changing the corneal curvature by their novel and unequal efforts to put and to keep the world right side up.

We believed it logical to hold that certain ocular muscles might become shortened by adaptation, in the same manner that the peronei in the leg shorten when the internal muscles stretch and let down under the increase weight caused by a disturbed line of gravity and that there was no reason why a tilted pelvis, for instance, should not produce compensatory changes in the eye structures as it will in foot structures.

On these assumptions several hundred consecutive eye cases were contrasted with the consecutive cases of postural defects appearing at the Crippled Children's Guild. In the former group, naturally, nothing like a full orthopedic examination, with the patient stripped, was possible. At first merely the binocular and monocular ductions were taken, together with the usual refractive findings, but later the fixing eye for distance and near was determined, the ocular torsions, the gross features of cranial and facial asymmetry were observed, as well as the location of a plumb line passing thru the external occipital protuberance and the position and degree of head-tilting, rotations and other cranial malpositions.

It was quickly found that among the cases which were without doubt primarily orthopedic, such as infantile paralysis, hip disease, tubercular disease of the spine etc., gross ocular muscle defects and irregular astigmatism, of notable degree, occurred in the proportion of about 3.2:1, when compared with the consecutive eye cases, the comparable cases among which, almost without exception were frankly out of skeletal alignment. A standard of over 3 degrees of left or right hyperphoria, of over 3 degrees of exophoria or esophoria, exophoria for near of 10 or more degrees and esophoria for near of any degree were taken as an empirical but practical basis for comparison. Left hyperphoria occurred in 72 per cent of the orthopedic cases and 61.5 per cent of the eye cases; and the characteristic ocular imbalance associated with the obvious postural imbalance was that of left hyperphoria; exophoria for distance and increased exophoria for near, due to weakness of the left internus, the right eye fixing both for distance and near, the left diverging at near, and the left eye showing torsion or cyclophoria. In the eye group it was seen that the great majority of patients complaining of suboccipital or cervical or brachial pains showed more or less obvious postural faults and a muscle balance corresponding to that of the characteristic orthopedic case. Every case of hyperphoria above five degrees in both groups showed more complicated head tilting and rotation, more obliquity of the shoulder-girdle and more marked spinal curves and rotations, than were to be found in the cases of lesser ocular inbalance.

Our first conclusions from the work begun in 1915 were reached in 1917. Orthopedic results in cases of serious deformities are obtained thru patient muscular, ligamentous and nervous re-education, and when our results appeared sufficiently suggestive to warrant publication, as well as to estab-

lish priority, Dr. Lowman, in February 1918, submitted the main orthopedic fiindings and the hypotheses then reached, in the form of a candidate's thesis to the Committee on Membership of the National Orthopedic Association. This paper appeared in the American Journal of Orthopedic Surgery, Dec. 1918, p. 459-492 with the title "The Effect of Faulty Skeletal Alignment Upon the Eyes."

Risley (Amer. Jour. of Ophthal., May 1918, p. 357) is reported to have made a study of a number of cases of decided cranial and facial asymmetry. Hatters forms were made of many of these and the grotesque distortion which these forms showed was frequently coincident with such marked facial asymmetry as a relatively flat or even concave zygoma on one side paired with a large convex one on the other, and with much variation in the distance of the eye from the median plane. This variation of the location of the eyes in the orbit, in the form of the globe, in the length, line of direction and point of origin and insertion of the extrinsic ocular muscles were considered by Risley to be large factors in producing the refractive defects and muscular imbalances noted in these cases. Risley made no observation of associated postural defects of cranio-spinal alignment.

Stevens (N. Y. Med. Jour., Aug. 17, 1918), writing on "Right Handedness in Its Relation to Visual Conditions," correctly interprets the unsymmetric shape of the skull as the direct effect of the over development of the motor area of the left cerebrum to correspond with the racial prevalence of dextrality. In infancy there is bilaterality of cortical movements which wrongfully undergo suppression in the infantile period as the result of prevalent racial training. Repeated examinations show that the cranial asymmetry which results produces a distortion of the left orbit, the upper arch of which is pushed out, thus changing the axis of the cavity and, as measured by the clinoscope, leading to a left cyclophoria, a fact wholly in accord with our clinical findings. In some cases Stevens noted a right cyclophoria or a cyclophoria of each eye, and finds that such deviations usually occur in the left handed or ambidextrous; or in those who were left handed or ambidextrous when young, but whose natural and instinctive manuality had been forced into dextrality to accord with popular opinion and action. Stevens accurately concludes that the lack of symmetry of ocular position associated with the cranial asymmetry, leads naturally to imperfect symmetry of action and to imperfections of binocular vision. He finally urges that ambidexterity be encouraged, a conclusion which, in our opinion, ought to be broadcasted with epigrams to the effect that "An unequal brain development makes an uneven mind" by which the idea may be popularized. Stevens made no observation of associated cranio-spinal alignment.

Verwey (Amer. Jour. of Ophthal., Sept. 1918, p. 677) reports the correction of heterophorias of low degree thru inclinations of the head.

De Kleijn (Archives neerlandaises de Physiologie, tome 11, p. 644, 1918) shows that in the rabbit, alterations in the posture of the neck, especially of the two upper segments, provoke and maintain definite posture of the eyeballs. From the experiments, accomplished by extirpating the otic labyrinths, Sherrington (Brain, London, Nov. 1918, p. 332-343), in a masterly deductive paper on "Observations on the Sensual Role of the Proprioceptive Nerve Supply of the Extrinsic Ocular Muscles," reaches the conclusions that "sensory impressions of the neck posture have probably to be added to the factors implicated in visual imperceptions of orientation as regards verticality and inclinations thereto," the other factors concerned in spatial orientation being; 1, the retinal proprioceptive; 2, the muscular sense derived from the proprioceptive nerve supply of the extrinsic ocular muscles; and 3, otic labyrinthism. Sherrington emphasizes the fact that spatial perceptions are by no means purely visual but are rather "visuo-musculo-labyrinthine," the afferent nerve fibers in the extrinsic ocu-

lar muscles yielding sensory impressions which are the basis of perception of postures and movements and which aid the proprioceptive nerves of the rest of the body, and especially those of the "gravitational labyrinth" in registering the attitude of the whole body and its relation or orientation to the vertical.

The logical practical deduction from Sherrington's work, which we feel justified in making in view of the abundance of our clinical proof, is that when one leg of this proprioceptive quadrangle is defective the others take up the increased burden of maintaining or attempting to maintain normal spatial orientation, or yield under the added effort. Thus an altered state of the muscles supporting the shoulder-girdle, neck and head, by deviating the head from verticality, may produce an altered static state of the extrinsic muscles of the eyeball, which causes altered muscular sensation in maintaining the eyeballs in their new postures. We believe that this altered sensation may evidence itself in any leg of the quadrangle by symptoms such as actual visual (retinal) tire, muscular imbalance, or actual equilibrial (otic) disorder.

The stimuli which evoke compensatory muscular action and altered sensation in the extrinsic ocular muscles appear to be both gravitational and visual (retinal), and represent an attempt to keep the world right side up and in line with visual perspective realized as correct thru prior experiences. The converse deduction may explain the difficulties evoked by the correction of gross refractive defects for the first time late in life. Here both muscle sense and visual sense have long united in the assumption that their faulty muscle pulls and imperfect vision were normal and their reeducation to a realization of normal orientation is often impossible.

Returning to the question of the origin of many of these deviations from normal: The racial training which assumes, erroneously, that dextrality rather than the inborn state of ambidexterity is the correct state of man, causes the relative enlargement of the motor area in the left hemisphere. This occurs during the plastic years of the infantile period when there is no bar to the consequent enlargement of the left side of the cranium which, in being more capacious than the right, and heavier of content, leads to asymmetry of the orbits, of the face, of the position of the eyes in the orbits and of the muscular distribution and action, the last being partly the result of the orbital asymmetry and partly the result of faults of spinal and hence of general posture.

For purposes of skeletal mechanics the skull must be considered as a terminal vertebra whose unevenly distributed weight is superimposed upon the atlas and axis and to balance which there has commonly been developed a long total left lateral spinal curvature which is as normal to all dextrous individuals as the corresponding long right total postural curve is to the sinistrous. In scoliosis studies the more common of these curves, the "total left postural" or "functional" curvature has been considered merely as an uncompensated curve due to relaxation, habit, overweighting, etc.; whereas, in fact we have what should be classed as a right cranio-cervical, left dorso-lumbar curvature, in strict orthopedic nomenclature.

Where there is bodily symmetry, or where all the forces making for asymmetry balance, the result is a vertical orthophoria, it being assumed in this entire consideration that no pathologic conditions as nasal sinus disease and no truly congenital anomalies exist to complicate the situation.

The lateral muscular balance we consider in the main the result of cranial, orbital and facial asymmetry as affecting the relative positions and musculature of the eyes and there is no doubt, from our demonstrations of complete ocular muscular readjustments to normal of lateral imbalances following spinal realignment, that cranial posture with regard to verticality, whether purely of spinal or of cranial origin, or the product of both, is the

activating factor in this, as in most ocular imbalance.

The relation of the shoulder-girdle to these problems is both close and interesting. The shoulder-girdle may be considered for purposes of the mechanics involved, as being slung from the neck and occiput by the trapezius and the deeper muscles, these muscles fixing the girdle in all finely coordinated work of the hands and arms, fixing the neck during all visual concentration, and being concerned in the sensory impressions of neck posture as regards to verticality. In the dextrous the greater weight of the right shoulder and arm causes this to sag, drooping the right side of the shoulder-girdle. The left shoulder rises correspondingly, while the head tilts or rotates (uncomplicated tilting is almost unknown) to produce a left hyperphoria or, if the tilting exactly compensates for the shoulder-girdle alteration, a vertical orthophoria. Hence the vertical ocular balance must be considered the product of the cranio-spinal curves and the shoulder-girdle position, according to the presence and degree of dextrality or sinistrality.

Other factors modify or complicate this common relation such as the faulty head postures which are beyond question the result of intrinsic heterophorias, if such a term may be coined to identify those due to muscular defects inherent in the position, distribution and action of the extrinsic ocular muscles by virtue of congenital or occupational faults, as opposed to the heterophorias which are demonstrably the result of original faults of skeletal posture. Among such skeletal changes we find those due to unilateral leg deformities and faults in pelvic alignment, and the various spinal deformities associated with faulty postural habits or the results of spinal pathology. In not every such case, however, are ocular anomalies found, as in the case of a woman of 47 with tubercular disease of the right hip dating from childhood, who wore a shoe raised two inches, but whose spinal curvature caused by the unequal length of the legs, was fully compensated by this shoe, by other curves above and by a head tilt which yielded a vertical and lateral orthophoria as the sum of all the forces.

In a large series of orthopedic cases under treatment, correct shoeing, corseting, bracing, massage, spinal manipulation, hydrotherapy, head suspension and gymnastics, led in a few months to several years, to a correction or beneficial modification of low degrees of muscle imbalance of all sorts, as well as to a lessening of astigmatism in some cases and to its complete cure in five.

The largest class of patients whose symptoms have previously been most distressing and most discouraging, because hitherto almost unrelievable, is that showing from 2 to 6 degrees of exophoria at distance, exophoria for near of from 9 to over 20 and usually variable, adduction equal to or often less than abduction, frontal, suboccipital and nuchal aching, provoked by close work and usually worse the following day, soreness at various points along the spine and with an increase in general nervous symptoms which has long since, unhappily, placed this large and important group of cases among the psychasthenics. Some of these cases have little or no refractive error, tho the majority show compound hyperopic astigmatism of moderate to considerable degree. Excluding amblyopia ex anopsia and visual disparity due to accidents, the right eye is, for the most part, the fixing eye both for distance and for near, the left eye diverges when test objects are brought near, the left eye is the higher, and its axis is tilted (cyclophoria, or the positive declination of Stevens), all of these being in line with the observations previously noted in connection with structural faults of the left orbit, of the musculature of the left eye and of general cranio-spinal asymmetry. A careful orthopedic examination shows that, with hardly an exception, these cases occur in connection with abnormal spinal twists and rotations, especially cervico-thoracic, with irregular and painful impingements of normal or of abnormally broad lateral processes, with overlapping impingements of

the posterior spinous processes in cervical lordosis, with arthritic enlargements of the articulations, fibrositis and periarticular thickenings due to ligamentous strain and trauma, cervical ribs, etc. Nearly all of these cases show muscular spasm and soreness, over the points of muscular and ligamentous insertion which are being unduly stretched as the effect of faulty skeletal alignment. A common fault is the lateral bending with rotation which occurs in scoliosis, where lateral and antero-posterior deviations of the shoulder-girdle exist with so much stretching of the brachial plexus as to cause brachial pain and incorrectly termed "brachial neuritis." The ocular disturbance so often associated is probably partly due to the reflex effect continuously produced in the cervical sympathetic.

In most of these cases the true relation between cause and effect is clearly shown by the more or less prompt relief to nervous, spinal and ocular symptoms which follows corrective orthopedic measures. In many cases where the abduction is weak the relief is distinctly accelerated by appropriate prism exercises, fixation exercises for improving the near balance, graduated reading and careful visual hygiene. In a few cases complete relief has not been obtained from these corrective measures. Possibly here the general postural asymmetry is excessive, and the uneven cranial weight and the uneven shoulder weight and action combine with occupational habits to maintain the postural fault to a degree.

Two practical points of ocular hygiene arise from this investigation: 1. In the cases which develop symptoms referred to the neck on close ocular fixation, attention should be given to correct seating, and to such cranio-cervical support and consequent relaxation that contraction of the erector spinae group cannot be maintained stiffly or, at least can be minimized. 2. In those cases where occupation demands ocular fixation combined with intense shoulder-girdle fixation, such as in sewing, reading and typing and especially when without arm support, the symptoms are often induced more by the weight of the hands, forearms and arms dragging upon the trapezius and keeping it contracted, than by the process of shoulder-girdle fixation alone. Here again the relief can be obtained by relaxation gained by correct seating, correct posture, by voluntary relaxation of the back and neck and especially by providing chairs with arms to relieve the shoulder-girdle of the pendant weight. Herein also lies the great value of the reading stand or rack which allows complete shoulder-girdle relaxation and permits the reader, as well, to assume a completely relaxed posture of head and spine.

The writer presents this elementary work, with all of its obvious imperfections, in the belief that a new point of attack and a means of prevention are shown against conditions, the persistence of which has been a source of discredit to ophthalmology, no less than to medicine as a whole.

Finally, the assistance and inspiration of Dr. Charles L. Lowman in this work are hereby acknowledged.

Conclusions: 1. We have established the first practical therapeutic connection, if not the first postural connection, between cranial asymmetry and spinal curvature.

2. We have made the first demonstrations that the common faults of head position, hitherto ascribed solely to faults of action and distribution of the extrinsic ocular muscles, often may be due to structural skeletal faults original in the lower extremities or spine; which affect the eyes thru their influence upon head posture, as well as thru their effect upon the cilio-spinal sympathetic center and the sympathetic pathways.

3. For the purpose of skeletal mechanics the head must be considered as a great terminal vertebra which assumes compensatory postures in the case of postural defects original in the extremities and spine, and gravitational postures due to its own imbalance on the spine, unless fully balanced by compensatory spinal curves.

4. Excluding conditions orginating from diseases, the basic skeletal faults

deemed responsible for many functional defects in the eyes and nose and, for much ocular and cranial pathology, are those arising from asymmetry of the cranium in connection with the racial prevalence of right handedness and the less common left handedness. From this asymmetry spring orbital distortions, and alterations in the positions, muscular distribution and muscular actions of the eyes, the left eye being mainly affected thru its proximity to the larger left cerebral hemisphere and the large left cranial fossae, and left hyperphoria, cyclophoria and left adductor weakness being the common muscular defects. From this common origin come also asymmetry of the facial bones, of the shape, position and ease of drainage of the nasal sinuses, and faults of the bony and cartilaginous septum, of the hard palate, the jaws and teeth.

5. To balance the unsymmetrically placed weight of the head on the spine long, lateral, compensatory curves of the spine are developed. These are exaggerated or further complicated by the effect of dextrality or of sinistrality in uncompensated shoulder-girdle deviations, which induce further changes in the posture of the head, thus neutralizing or exaggerating the cranial posture which would otherwise have resulted.

6. These faults of cranial posture influence the proprioceptive functions of the extrinsic ocular muscles, the retina and the muscles of the neck, and undoubtedly put more strain upon the labyrinthine mechanism in their efforts to readjust the ocular position with regard to verticality, or spatial orientation.

7. Stabilization of the head on the neck and shoulders is almost as essential to all intense and prolonged ocular fixation as the more limited action of the extrinsic ocular muscles. Stabilization of the shoulder-girdle is equally an essential, when finely coordinated manual work is the object of the ocular attention. Strains of this stabilizing system thru its overuse, and especially in the presence of spinal faults and uncompensated shoulder-girdle deviations, produce the distressing suboccipital, cervical and brachial symptoms incident to reading and to many occupations.

8. Severe ocular imbalance is found more commonly among cases which are primarily orthopedic than among average eye cases. Cranio-spinal postural defects are found almost uniformly in the eye cases complaining of suboccipital and nuchal aching and are, in the main, capable of relief or cure by methods of relaxation and by appropriate orthopedic and ophthalmic procedure. As a result of such treatment we have noted the lessening and disappearance of ocular muscle imbalance and, in a few cases, the lessening or disappearance of corneal astigmatism. (Our original investigation was limited to the relation of postural and eye-muscle defects; and it is likely that complete comparisons of the corneal astigmatism before and after alignment would have given a much higher number showing astigmatic changes.)

9. The logical applications of our work to preventative medicine are, (a) Ambidexterity must be insisted upon during the infantile period and the plastic, developmental years. This will produce not only the symmetric development of the cerebral hemispheres, but is the means of symmetric development of the cranium and of the superficial and deep components of the face. In this way developmental malpositions of the orbits, the eyes, the nasal cavities, jaws, teeth and spine will be prevented and the pathology which has its foundation in these early defects will be avoided.

(b) The prevention of ocular faults resulting from faulty spinal alignment lies, obviously, in the early recognition of the spinal defects by the pediatrist and by those responsible for our school hygiene, and in their cure in youth by the orthopedic surgeon.

THE CONTROL OF TRACHOMA AMONG THE ALIEN LABOR COMPANIES OF THE BRITISH AND AMERICAN EXPEDITIONARY FORCES

GEORGE S. DERBY, M. D., F. A. C. S.

BOSTON, MASS.

As Lieut.-Col. and Assistant Ophthalmic Consultant of the American Expeditionary Forces, Dr. Derby had to deal with the problem of trachoma. He here describes the classification, segregation, and treatment of the infected men. Presented to the Section on Ophthalmology, American Medical Association, June 11th, 1919.

Civilian labor was employed to a very considerable extent in France by the French, British and American forces. In many instances, these laborers were drawn from races in which trachoma is a common disease, and a large number of the individual laborers were themselves infected.

The history of the spread of trachoma among the armies of the various nations, before proper methods of control were in force, is well known. A few figures taken from Eason's article read at the 1918 meeting of the Ophthalmological Society of the United Kingdom may be given here. On the invalid list of the British Army during 1818 were more than 5,000 soldiers rendered blind by trachoma. From 1813 to 1817, from 20,000 to 30,000 men of the Prussian Army were affected. From 1816 to 1839, over 76,000 men in the Russian Army were trachomatous. A Belgian Army was disbanded because the disease was so prevalent and spread infection thereby thruout the civilian population.

The introduction of alien labor companies into France, in some of which trachoma was prevalent, brought a certain amount of danger to the civilian population and to the armies themselves. It was my fortune, while stationed with the B. E. F., in 1917 and part of 1918, to have an opportunity to study the British system of trachoma control and to take a small part in some of their work. Later, the task of inspecting the labor companies in the American Expeditionary Forces for trachoma was assigned to me, and as our plans for this work were modeled entirely on the system so admirably carried out by the British, I may be permitted to give a rather full description of their work.

BRITISH EXPEDITIONARY FORCES.

In the spring of 1917, the disease was noted among the Egyptians and Chinese to a considerable extent, and it was decided, after a consultation held between Colonel W. T. Lister and Major J. F. Cunningham of the Ophthalmic Consulting Service with the various army authorities interested, that a complete examination of these nationalities should be made. Orders were immediately sent out to the effect that "no cases with definite trachoma granulations or acute conjunctivitis be allowed to embark from Egypt or China or disembark in this country." Of several thousand Egyptians it was found that 19 per cent had active trachoma, and a serious problem arose as to the handling of them. They had been enlisted in groups in Egypt, each group under its own headman, and they could not be separated from him. Luckily, their stay in France was to be a short one, and therefore the measures employed in general were segregation, disinfection and treatment in each company.

The main problem was among the Chinese, for they came to stay and in large numbers,—over 100,000. There was some difficulty at first, as companies had been sent out in which a certain number of trachoma and conjunctivitis cases were mixed in with the clean men. As time went on, however, and the system became established, it was possible to remove the infected ones from these companies and to replace them.

Under the energetic guidance of Colonel Lister, the Ophthalmic Con-

sultant, and of Major J. F. Cunningham, a most excellent system was established and began to work in July, 1917. On the arrival of each shipload of men at Chinese headquarters, in addition to a general examination each man had to have his lids turned and inspected. These inspections were carried out by men familiar with the disease. If the lids were healthy and there was no conjunctivitis, the man was placed in a clean or "X Company." When conjunctivitis was discovered and no evidence of trachoma, the man owing to the difficulties of obtaining coolies entirely free from the disease, a certain number of trachomatous cases came over with practically every shipment, tho the number showed a very satisfactory diminution as time went on. It was impossible to hold clean men at headquarters for a sufficient length of time to rule out contagion, and therefore it was to be expected that trachoma would appear from time to time in the clean companies, as it did, since all these men were contact cases.

Fig. 1. Labor company in France drawn up for inspection.

was placed in a conjunctivitis or "Y Company." Trachoma cases were put in trachoma or "Z Companies." Doubtful cases of trachoma were usually placed in the "Y Companies." These labor companies were usually formed of 500 men, and were sent out from headquarters to the various areas where labor was required.

Clean companies, under medical officers without ophthalmic experience, could be sent anywhere, so long as provision was made for occasional inspections by ophthalmic specialists. These inspections were necessary, for although directions had been sent to China not to embark infected men, yet, The Y and Z cases were sent to places designated as "Trachoma Treatment Centers," where they were under the supervision and care of an ophthalmologist.

Examination carried out at Chinese Headquarters over a period of nine months showed that 5.04 per cent of the Chinese arriving had active trachoma, while 13.49 per cent had conjunctivitis, and many of these latter were well on their way to recovery from treatment received before they were sent out, and it was possible to place them in clean companies. The trachoma figures did not include a number of the early companies in

which the percentage of disease was large. Colonel Lister's figures in a report sent in a few months ago show, among 100,000 Chinese, approximately 8,500 cases of acute infectious trachoma and 5,500 cases of suspicious conjunctivitis.

Inspections of companies in the field were carried out by Colonel Lister and his assistants at frequent intervals, care being taken to examine the men at a time when it would interfere with labor as little as possible. Owing to the central location of Colonel Lister's headquarters (Boulogne) in relation to the British front, it was possible to examine a number of companies on a single day if the schedule was well planned. The Chinese were lined up in three or four files, according to whether three or four officers were to make the inspection, and came up in turn for the examination. Behind the examining officers sat the recorder at a table. Clean cases were immediately passed. If a conjunctivitis or trachoma case was detected, the man was detained by a non-commissioned officer, his number ascertained from his identity disk or wrist band, and it was recorded in the appropriate column of the recorder's book. The number examined was also recorded, so that there was a permanent record of all cases of disease and the men could be transferred to their proper companies. One copy of the record was left with the company. Under the system adopted, these examinations were carried out with great speed. With three medical officers examining 500 men could be gone over in 25 to 30 minutes.

Fig. 2. Method of inspecting the eyes for trachoma, four officers inspecting, recorder taking number of man found infected.

TREATMENT—As the Chinaman is prone to develop conjunctivitis, especially if working in a dusty atmosphere, Coloned Lister instituted the so-called "Universal Drops" treatment for the clean companies. This consisted in dropping a solution of zinc sulphat and boric acid into the eyes of each man once a day, preferably after returning from work. The men were taught to squat down in two long rows facing each other and to draw down the lower lids with the fingers. A Chinese medical orderly passed down in front of each one and instilled the drops. He was assisted by a man who passed behind the row and steadied the head

of each individual. As each row was treated, it was replaced by another, and the whole company was finished in about twenty minutes. The milder cases in the Conjunctivitis (Y) Companies were treated in the same way. In severe cases the lids were painted with silver nitrat or protargol.

Trachoma (Z) Companies had the treatment appropriate for each case—expression, silver nitrat, or the copper stick. Corneal ulcers were treated as in civil practice. An important factor in the limitation of the spread of this disease was regular sterilization of the Chinaman's towel twice a week.

By the procedure described it was not expected that these laborers would be cured of their trachoma, but it was expected that the spread of the disease would be limited, and that their working efficiency would be raised to the highest point practicable. I believe that these ends were accomplished. Trachoma if untreated leads to a loss of working power.

To quote from Colonel Lister's report: "The first examination of two (of the earlier) companies revealed 12 cases in one and 15 in the other. Owing to the importance of the disease not being recognized by the authorities, the treatment advised was not carried out and the notified cases of trachoma were not moved. In eight week's time there were 59 cases in one company and 81 in the other."

"A trachoma company was sent up to an army area for about six weeks and was untreated. At the end of this time the average number of men off duty daily for eye trouble was 30, and 15 men had been sent down to Headquarters as unfit to work."

This last company was sent down to the Base and was put under the treatment of Captain Hine, Ophthalmic Specialist at Camiers, with whom I saw them in October, 1917. Out of 588 men, 68 needed expression. From 30 off duty daily in October, the number fell under proper treatment to 7 in December and 2 in January. In two other companies the number off duty fell in four months from twenty-five to none.

No case came to notice of the disease having spread either to the civilian population or to troops. The Controller of Labor has stated that the men off duty in the affected companies was no greater than in the unaffected com-

Fig. 3. Men lined up to receive treatment for conjunctivitis and trachoma.

panies. Not more than two or three patients a month were sent back to Chinese Headquarters as unfit to work.

A system of ophthalmic reports was instituted giving the essential facts as to eye disease in each company, including the number of men off duty daily for eye disease. By a glance at these cards it was possible to see which companies were in need of attention. A system was also instituted by which

Fig 4. Method of instilling drops while assistant steadies the head.

the various areas of the British Expeditionary Force were divided so that sufficient inspections could be made.

American Expeditionary Forces.—In July, 1918 the Division of Ophthalmology of the American Expeditionary Force was asked by the Medical Division of the Labor Bureau to make an inspection of the administrative labor companies, with a view to ascertaining the amount of trachoma existing and to suggest any necesary measures for its control. This duty was assigned to me by Leuitenant-Colonel Greenwood the Senior Ophthalmic Consultant. A conference was held in Paris with Major W. H. Honor, the Chief of the Medical Division of the Labor Bureau, who, like myself, had served with the British Expeditionary Force and was familiar with the British trachoma problem and the way in which it had been handled. We agreed that our work should be carried out along the same general lines, but adapted to the special conditions which existed in the American Expeditionary Force.

We had in the neighborhood of 180 companies to be inspected, scattered over the whole area of France occupied by the American Expeditionary Force, from the aerodromes close to the front, back to Bordeaux and the other Base Ports. The companies were all taken over from the French, who organized them, and were all inspected by the French for contagious eye disease at

the various centers at which they were gathered together. Their disciplinary control was in the hands of the French, a fact which created difficulty in a number of instances. Racially, they could be divided into Chinese, Indo-Chinese, North Africans and mixed. The North Africans were composed of several different races—Moroccans, Algerians, Tunisians, etc. There were French Companies, Spanish Companies, many Portugese and other nationalities, but these for convenience we classified as mixed.

The work of inspecting the companies in the advance zone began on August 7. In general, the companies were notified several days in advance that an inspection would be made at a certain hour. The hour was chosen so as to interfere as little as possible with the labor of the company. In some cases the companies were examined on Saturady afternoon after working hours, and in some cases on Sundays. In certain instances, inspections were held before the men went to work or after returning from work,

Fig. 5. Method of watching progress of infected cases.

Owing to the pressure of the other duties, it was impossible for me to devote a continuous period to this survey, and the examinations were spread over a period of four months. The companies in the advance zone were covered by short trips from the Medical Consultants' Headquarters at Neufchateau, while those in the intermediate and base sections were covered by a special tour beginning on October 10 and ending November 10.

Our companies were small, sometimes not more than 50 men and never more than 300. They were very widely scattered and engaged on all sorts of projects.

during the period when the light of the summer season permitted. In the majority of cases, the work was done either just before or after the noon meal. There was no uniform schedule of labor for these companies. Some did not work the latter part of Saturday afternoon and some did not work on Sunday, and it was difficult to hold them for examination outside of their working hours. Inspections were, (in all but two instances) carried out by me; usually with one assistant, sometimes more.

The technic of the examination was that used by the British, already described. A record was made of the

individual numbers of the men affected. A copy of this record was left with the company, a copy was sent to the Medical Division of the Labor Bureau, and a copy filed in the Consultants' office. Thus, at the end of the inspection we had a record of all the diseased cases found at the time of the examination.

Cases were classified as Z, or trachoma, only when the diagnosis was evident. All doubtful cases were classed as Y, or conjunctivitis. In the Y class it was attempted to put only doubtful cases of trachoma and cases of conjunctivitis with secretion which appeared to be contagious. During the examinations, quite a number of cases of old trachoma, noncontagious, with smooth conjuntiva and old scars were encountered. These were passed as being harmless. The largest number of this group appeared among the North Africans. A number of eye conditions other than conjunctivitis were discovered and their treatment provided for.

Fig. 6. Men bringing their towels for disinfection.

Our figures show that 12,461 laborers were examined; and that among them were 1,618 cases of conjunctivitis, 13 per cent; and 261 cases of trachoma, 2 per cent. If we separate the nationalities we find:

1. Northern Chinese, 4,958 examined; 1,090 with conjunctivitis, 21 per cent; and 160 with trachoma, 3.2 per cent.

2. Indo-Chinese, 1,795 examined; 284 with conjunctivitis, 16 per cent; and 44 with trachoma, 2.4 per cent.

3. North Africans, 1,291 examined; 51 with conjunctivitis, 4 per cent; and 18 with trachoma, 1.5 per cent.

4. Mixed, 4,417 examined; 193 with conjunctivitis, 4.3 per cent; and 39 with trachoma, 0.9 per cent.

As noted before, the North Africans showed a large percentage of healed trachoma.

Our percentage of trachoma among the Northern Chinese (3.2 per cent) is much lower than that found at first by the British (8.5 per cent), but compares well with their later shipments. This may be accounted for by the fact that a number of our Chinese companies examined had already been gone over and the cases of trachoma weeded out. Several of the companies that had been previously weeded out, however,

showed a number of fresh cases of trachoma and a considerable amount of conjunctivitis. As a rule, the trachoma seen among our Chinese was in an early stage. In very few cases was it disabling.

As it was not possible in the beginning to follow the British lead and establish conjunctivitis and trachoma companies for the diseased eyes, it was decided temporarily to look after them in each company, as no other course remained open to us under the circumstances. A circular was therefore drawn up and sent out to every company by the Labor Bureau describing the purpose of the examination and the various measures to be employed. After the examination of each company, or of each group of companies when more than one were in the same area, the Commanders of companies, the Medical Officers responsible for them, and when possible the Ophthalmic Specialist attached to the nearest hospital, were gathered together and the situation was thoroly discussed and instructions given for the isolation and treatment of the Y and Z groups.

In many instances, the companies were in fairly close proximity to a Base or Camp Hospital at which there was an ophthalmologist stationed. He was informed of the policy decided on, and the general direction of the eye situation was intrusted to him. Active cases of trachoma were treated by him, as were those of the conjunctivitis group which needed special treatment.

A report was made to the Chief Surgeon of the American Expeditionary Forces, and to the Labor Bureau, giving in detail the figures of the various companies and the following recommendations were made:

"Trachoma cases should be isolated in special companies. These companies should be worked in some hospital area where they can be under the supervision and care of the Ophthalmic Specialist. The Director of the Labor Bureau has already ordered the formation of a trachoma company at a hospital center." Until these trachoma or Z cases could be transferred to such a company, instructions were given to include them with the Y or conjunctivitis cases.

"Conjunctivitis cases (Y) should also be put in special companies and given appropriate treatment. Until this can be carried out, the following course should be adopted, and the Commanding Officers of all companies have been instructed in the procedure. The men should be isolated in a separate barracks or part of a barracks. They should, as far as possible, wash separately, eat separately and work separately from the clean men. Their towels should be boiled for thirty minutes twice a week, as should handkerchief when in use. Local treatment consists in the administration of zinc sulphat drops (.3 per cent) twice a day. This treatment may and should be carried out without interfering with labor."

A detailed description of the British system of using the "Universal Drops" was then given as already quoted.

"The Y, or Conjunctivitis cases, should be examined by an Ophthalmic Specialist every three weeks. In six weeks, it should be possible to tell which of the suspicious cases are in all probability trachoma, and measures taken accordingly. Where trachoma has existed in a company, a certain number of the X, or clean, men will later develop it, and these must be carefully watched for. Unfortunately, labor companies move so frequently that arrangements for the supervision of the Y cases will break down in many instances under this system. If alien labor companies, especially Chinese, are to be employed for any long period of time by the American Expeditionary Forces, some provision for the formation of Y companies should be made."

"Clean (X) Companies.—The Medical Officer in charge of X Companies should be on the constant lookout for fresh cases of eye disease. If these cases do not respond to treatment in a short period of time, the advice of the nearest Ophthalmologist should be sought."

It should be remembered, in con-

sidering the trachoma problem, that the ordinary methods of handling trachoma in civil life do not apply here. We were in France to help win the war, and it was our duty to help the labor authorities by every means in our power by getting every possible ounce of work out of the labor companies. The British had shown conclusively that under a well organized system the disease could be controlled and labor rendered more, rather than less, efficient. Moreover, in the busy times we faced it was impossible to occupy hospital beds with any considerable number of trachoma cases. Rather than do this, the authorities preferred to send the laborers home, and in but few instances was this necessary.

A comparatively small number of cases of trachoma was found among our soldiers in France, and the proposal was made by the Senior Ophthalmic Consultant to the Chief Surgeon's Office that all such cases be segregated in a hospital area where they could have proper treatment and could be used as labor. On the ground that there were not enough of them to make this procedure worth while, this suggestion was not acted on, and they were held for treatment in the various hospitals.

In a large part of the inspection Lieutenant-Colonel Nelson M. Black, M. C., was associated with me and was of the greatest assistance. At times when Lieutenant-Colonel Black was not available. I was very efficiently aided by Lt. H. B. Chandler, M. C.; Captain Ralph Hatch, M. C.; Lt. R. J. Sprowl, M. C.; Captain Lloyd Whitham, M. C.; Captain C. F. Jump, M. C.; Major George W. Jean, M. C. At all times the assistance and cooperation of the Medical Division of the Labor Bureau was given without stint.

I feel strongly that the Ophthalmic Service of the American Expeditionary Forces owes a very large debt of gratitude to the British Service, not only in the special line of trachoma, but in many other ways. Many features of the admirable system developed by Colonel W. T. Lister, ably seconded by Major J. F. Cunningham, were taken over by us and added greatly to the development of our service.

The following circular was issued by the labor bureau for the instruction of their officers and personnel:

AMERICAN EXPEDITIONARY FORCES

Labor Bureau, A. S. C.,
Office of Surgeon,
Medical Division, A. P. O. 717,
France, Oct. 21, 1918.

Circular No. 4.

To Medical Officers Assigned to Administrative Labor Companies.
(Through Commanding Officers.)

1. A survey is now being made of the Administrative Labor Companies, A. S. C., under the direction of the Medical Division, Labor Bureau, by the authority of the Chief Surgeon American Expeditionary Forces, as described in Circular No. 2, Medical Division, Labor Bureau, Aug. 7, 1918. The purpose of this survey is to determine the extent of contagious eye diseases with the view of preventing infection and promoting efficiency.

2. Administrative Labor Companies, especially those composed of Chinese and Indo-Chinese, are frequently liable to two contagious eye diseases, Conjunctivitis (pink eyes), often in its chronic form, and Trachoma.

Conjunctivitis is a contagious eye disease which spreads rapidly by contact. It is, however, readily curable under proper treatment, and suitable precautions will limit its spread.

Trachoma is likewise contagious; but unlike conjunctivitis, it is very resistant to treatment and in its more severe forms produces irreparable damage to the eyes and may interfere seriously with the efficiency of laborers infected. Certain early cases of trachoma are impossible to distinguish from chronic conjunctivitis until they have been for some time under observation. The spread of trachoma may be checked by suitable measures. Proper treatment will arrest its progress.

Contagion. Both diseases are con-

veyed from one individual to another by direct contact with secretion from the affected eyes, by personal contact, by infected towels and by the use of the same wash basins. Cleanliness is the greatest enemy of these diseases.

Classification. The present survey will divide the laborers of each company into three classes:

Class X comprises the individuals with clean eyes.

Class Y comprises laborers with conjunctivitis. A few of these may later show trachoma.

Class Z—Trachoma cases.

3. As a *Preventive* measure in all labor companies, each man should have his individual towel and soap. Towels should be boiled for thirty minutes twice a week. The same should apply to handkerchiefs.

Class Y should be isolated so far as possible without interfering with their labor. They should live in a separate hut from Class X, or, at least, a portion of a hut should be partitioned off for their use. They should wash separately and eat separately from Class X, and should work in a squad by themselves as far as is possible.

Local treatment of Class Y need in no way interfere with their labor. An aqueous solution containing one-third of one per cent Zinc Sulphate and two percent Boric Acid is used.

This treatment is best carried out in the following manner: At a suitable time before going to work and after returning from it, Class Y cases report for treatment. They squat down on the ground in one or more lines, pull down their lower lids and look upward. The Medical Orderly passes along the lines with an assistant. The assistant, who stands behind the laborer, steadies the head with his hands, the Medical Orderly in front instills with a dropper one or two drops of the Zinc Sulphate solution which he carries in a small glass. This procedure may be carried out easily without having the dropper come in contact with the eye that is being treated. An orderly may be quickly trained in this work. By this method, up to one hundred cases may be treated in fifteen minutes. After the application of Zinc Sulphate, the eyes will smart for from one to five minutes, but not longer.

4. Z *Cases* will be reported by number to the Medical Division, Labor Bureau, A. P. O. 717. Orders will be issued transferring them to special trachoma companies. During the interval between the discovery of trachoma Z cases and their removal, they will be subject to the same precautions and treatment as pertains to Class Y. If due precautions, as outlined, are observed, laborers infected with conjunctivitis, X cases, and trachoma, Z cases, may be handled without danger of infection to other laborers or troops.

GRANULOMA OF THE CORNEA

M. Feingold, M.D.

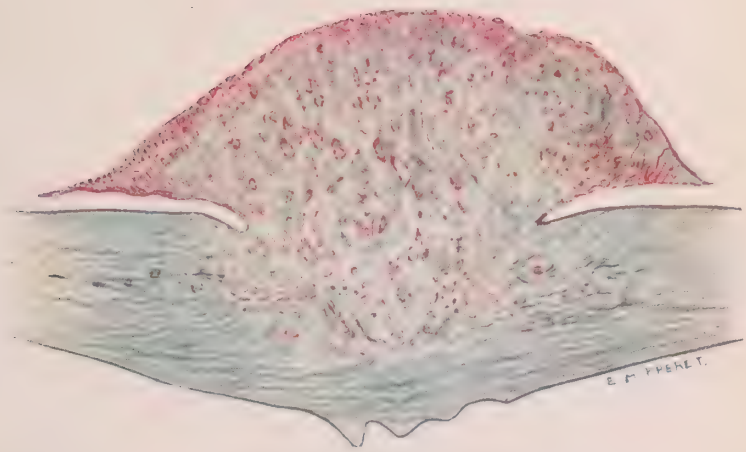
NEW ORLEANS

With reports of two cases, this paper gives a critical review of the literature, and draws the conclusions it seems to justify. Read before the American Academy of Ophthalmology and Oto-Laryngology, August 5, 1918.

Possibly no structure of the body has been the subject of so much study, clinically and especially experimentally, as, owing to its peculiarities, the cornea. But in spite of the many varieties of corneal affections described, and tho the process of healing of wounds of all kinds of this structure, has been studied and recorded minutely, one fails to find, even in the best and most modern textbooks, any mention of granuloma formation of the cornea. For this reason, the following cases seem to deserve recording, and a review of the few cases reported in the literature might not be amiss. This seems especially desirable since some of the case literature is not easily accessible and because the condition is generally placed among the tumors of the cornea instead of among the inflammations and their consequences.

Case 1.—H. J., colored, laborer, aged 56, applied at the Charity Hospital Eye Clinic, Nov. 9, 1917, stating that, three weeks before, muriatic acid had splashed into his eyes and that the right one was so badly injured by it that enucleation had to be done two weeks later. The conjunctiva of the eyeball appeared reddish white, the whole cornea grayish, and he could notice hand movements. Gradually a grayish-red soft granuloma 3 by 3 by 2 mm. appeared on the conjunctiva of the eyeball at the lower temporal limbus, and a similar flat one 3 by 1.5 mm. at the upper temporal limbus.

Dec. 6, 1917, the lower granuloma was seen riding on the limbus with its greatest portion on the cornea, while the smaller granuloma was entirely on the cornea near the upper limbus. The cornea appeared at first glimpse quite clear in the peripheral portion, but this was due only to invasion of superficial and deeper vessels from all sides; thru it, the iris could be guessed at. The central portion was whitish opaque and slightly depressed, with irregular surface. Light projection and color perception were good.



Later the upper granuloma moved 2 mm. from the limbus to the center getting smaller at the same time and appearing more red; the lower granuloma also grew smaller and more flat. The central area of the cornea became more bluish white and smaller, because encroached upon by the increasing ring of vascularization; the thickened grayish-red conjunctiva of the eyeball extended on to the cornea forming a false pterygium in several places. This was especially noticeable at the seat of the lower granuloma, which in the meantime had moved away from the limbus, leaving a narrow band of cornea between itself and the limbus. The upper nasal portion of the cornea cleared perceptibly and the patient could see faces.

Three months after the accident, the lower granuloma was smaller, triangular, and apparently pedunculated while the upper granuloma had entirely disappeared. During the further observation even the lower granuloma faded away gradually and the whole cornea cleared sufficiently so that, about May 1, 1918, patient could read 2-inch letters close to the eye. During the whole time the tension was carefully watched and always found to be below normal on palpation. Only once did the tension seem to be increased. Treatment consisted only in inspersion of ethyl-morphin hydrochlorid powder. See Fig. 1, Plate XI.

Case 2.—E. B., a farmer, aged 42, called at the Charity Hospital Eye Clinic, Sept. 29, 1915, because of inflammation of his right eye, which had begun when some unslacked lime got

CASE 1. GRANULOMAS OF THE SCLEROCOREA.

CASE 2. GRANULOMA OF CORNEA. MALLORYS CONNECTIVE TISSUE STAIN: X24.

into his eye three weeks before. The eye showed moderate ciliary injection; the corneal epithelium was markedly defective, the cornea itself diffusely nonsaturated, bluish, opaque with a deep seated, round, 3 mm. gray infiltration slightly below the center. There were 3 mm. of hypopon.

The hypopyon soon became absorbed but recurred several times. Gradually a small, soft, redish-gray tumor of granulation tissue appeared near the center of the cornea. Acetylsalicylic acid, ethyl-morphin hydrochlorid, argyrol, atropin, and physostigmin (eserin) were used to meet symptoms and indications. Repeated attacks of severe pain caused by increased intraocular tension finally necessitated enucleation which was done under local anesthesia, March 20, 1916. The eyeball was immediately placed in Zenker's solution, after hardening bisected in the equator and sectioned horizontally by Lee's dry celloidin method.

Histologic examination.—In the conjunctiva only a few plasma cells are seen, but the epithelial cells have a tendency to desquamation. The cornea is slightly pressed in toward the anterior chamber in the central part. This was apparently caused by the lid bulging the softened cornea in, when pressing on the projecting growth. The cornea is about 0.6 mm. thick in the periphery, somewhat thicker in the central portion. Here a mushroom-like growth is lying on the surface and is continuous with the corneal substance by its very short pedicle. The epithelium is missing on the whole corneal surface. At the limbus the epithelium of the conjunctiva projects for a short distance over the cornea, but is not in contact with it, forming a folded band which often folds back on itself toward the limbus. See Fig. 2, Plate XI.

But for an isolated, cell-like structure here and there, Bowman's membrane is entirely bare of epithelium. It is continuous over the whole surface of the cornea, except for about 0.98 mm. in the center corresponding to the pedicle of the growth. It is about 16 microns thick and seems to consist of two portions. The superficial one is about 3 microns thick and stains rather deeply with hematoxlyin and purplish with Mallory's connective tissue stain. The posterior portion stains more like the corneal substance. The anterior portion splinters off here and there to some extent from the underlying portion. Bowman's membrane, and to a slighter extent the adjoining lamellae of the cornea, contain numerous, small, amorphous and more crystalline, yellowish brown particles of different size (argyrol?). Bowman's membrane is everywhere in normal contact with the underlying parenchyma. In some sections, near the pedicle of the growth, masses staining intensely blue with hematoxlyin are seen between Bowman's membrane and the parenchyma and also in the spaces between the next three or four layers adjoining. These masses are fine and linear or more lumpy and often mask the corneal struture entirely (lime?). Numerous vessels pervade the whole cornea, lying mostly in the anterior two thirds. A few smaller vessels are immediately below Bowman's membrane. In the immediate neighborhood of all the vessels are seen cells, each with a long nucleus, staining deeper than the corneal cells, also an occasional eosinophil. The whole cornea is seemingly unaltered except that the fixed cells are evidently more numerous than normal. Higher magnification reveals some of these, at least, as possibly wandering cells, since their nuclei stain deeper blue and since two or three cells are at times seen in the same space. Except for the affected area, the cornea shows no differences in the arrangement and appearance as to color, etc., of the lamellae, in spite of the marked opacity in vivo.

The affected area is about 2.8 mm. in the largest diameter and is consequently larger than the defect in Bowman's membrane. It is roughly lenticular in cross section, that is, thickest in the center. It occupies the middle layers of the cornea, leaving the posterior fourth entirely free. Its edges are entirely in the deeper layers with comparatively unaffected corneal substance in front of it. Over the central

portion, on the other hand, corresponding to the defect in Bowman's membrane, this area extends even thru the anterior layers, and is here continuous with and forms the pedicle of the mushroom-like growth on the surface. In the affected area, the lamellae have lost their parallel arrangement, have changed direction, and have a tendency to bend forward into the pedicle. The lamellae are more widely separated and are possibly fewer in the center. The vessels are very numerous, especially near the pedicle. Between the separated lamellae and surrounding the blood vessels, numerous cells of the following types are found: (1) cells, each with a large, pale vesicular nucleus: endothelial and young connective tissue cells; the nucleus is often smaller and distorted by the surrounding tissue; (2) plasma cells; (3) polymorphonuclear leukocytes; (4) occasional eosinophilic leukocytes; (5) small, round cells, apparently lymphocytes; (6) cells in mitosis, most probably of the type mentioned in Group 1. The character and arrangement of the cells varies from place to place. Here the plasma cells prevail, there the polymorphonuclear leukocytes, etc.

The growth projects above the surface of the cornea about 0.93 mm. and is about 2.25 mm. in the greatest meridional diameter. It is button or mushroom-like, overlapping the cornea because it is bigger than the opening in Bowman's membrane, through which it is continuous with the corneal substance. Only in a small area does the growth appear more sloping on the surface and not overhanging. It is not covered by epithelium. On and near the surface, a network of fine fibers, arranged more or less parallel with it, is seen. These fibers have all the appearance of fibrin. Here they enclose an edematous area, there the network contains numerous leukocytes and traces of extravasated blood in other places. The skeleton of the growth is made up of more or less radially arranged fan-rib-like septums of connective tissue and possibly of some remnants of corneal tissue. Small and large vessels often showing bifurcations are very numerous. The vessels are arranged in a fanlike manner as in papilloma and near the surface are seen rather large sinus-like cross sections, filled with blood. The space between the connective tissues groundwork and the vessels is filed with cells of various character. They are all of the same nature as those of the affected area of the cornea, but are more numerous and the relative frequency is here different, the cells having large, pale, oval nuclei, and the leukocytes generally prevail. Plasma cells are also more often seen than in the cornea.

Behind the affected area more numerous nuclei are seen than in the balance of the cornea. The posterior surface of the cornea bulges somewhat toward the anterior chamber and shows undulations. These are due to wrinkling of Descemet's membrane which forms archlike projections into the chamber. There is no break in Descemet's membrane. These arch formations seem to be partly empty; partly they contain fine granular coagulum staining pink with eosin and partly some stratified tissue rich in nuclei, resembling the adjoining cornea.

Over the central part of the cornea, the endothelial cells are almost entirely missing; an occasional cell on the posterior surface of Descemet's membrane cannot positively be identified as such and resembles more a lymphoid cell. Only near the angles of the chamber are the endothelial cells forming a continuous layer, but are even here fewer than in the normal eye.

The anterior chamber is about 1 mm. deep in the center. The angle is perfectly free in most sections and the structures surrounding it are almost normal; in a few sections, a peripheral adhesion of the iris to the cornea measuring about 0.4 mm. is seen. The anterior chamber contains only a slight amount of granular, pinkish staining coagulum containing a few cells of lymphoid character.

A small focus of lymphoid cell infiltration is found in the iris root and a similar one near the sphincter. A small, broken-up posterior synechia exists in the pupillary margin. Ciliary body, choroid and

the other structures show nothing of interest. There is no glaucomatous cup.

NATURE OF THESE CASES.

From the description, it is quite clear that Case 2, showed the characteristic symptoms of corneal burns, not the subject of this paper, such as loosening and desquamation of the conjunctival epithelium, failure of the corneal epithelium to adhere, etc., together with a condition in the cornea, having all the histologic characteristics of a granuloma, which had developed in the anterior layer and on the surface near the center as a result of the destruction of the corneal tissue by lime. The clinical course of the first case makes it almost certain, in spite of the lacking histologic examination, that here also the growths were pure granulomas. These, tho ultimately situated on the cornea, had their beginning in the conjunctiva of the eyeball near the limbus. With the advancing clearing of the necrotic area, the granulomas advanced more toward the center of the cornea, shrinking in the periphery on account of the scar formation at the rear, until ultimately all the remaining granulomatous tissue was choked off by the scar formation and the accompanying reduction of the blood supply.

A search of the literature for cases of true granuloma of the cornea will have to exclude at the outset the formations of granuloma tissue as the result of tuberculosis and leprosy. These cases undoubtedly belong to a different class, as is already evidenced by the etiology. One cannot positively class with these cases Bock's reports of granuloma following parenchymatous keratitis, on account of our present view concerning syphilitic parenchymatous keratitis.

TYPES OF GRANULOMAS.

If we thus limit ourselves to the pure granulomas of the cornea, it is for practical reasons advisable to divide them into the following three groups:

1. Granuloma in the region of the cornea, the result of a prolapse of the iris following perforation; this might properly be called granuloma of the *pseudocornea.*

2. Granuloma of the cornea extending from the conjunctiva of the eyeball near the limbus after injuries, etc.; granuloma of the *sclerocornea.*

3. Granuloma of the cornea, developing away from the limbus and not the result of perforation; granuloma of the cornea proper.

1. It is evident that the cases of our first group cannot be classed as granulomas of the cornea, but they are here considered for purely external reasons only. While not very frequent, they are more often to be observed than the other two forms of granuloma. In our second case, a superficial examination gave one the impression of a granuloma of this kind, as depicted by Parsons, Fig. 103. In Blaskovics' case, to be mentioned later, this possibility was also considered. In this group belong the two cases of Sichel, his observations 205 and 206, since perforation of the cornea had occurred in both instances. The case of Schmidt-Rimpler was probably of the same kind. His patient, a young laborer, after getting lime in both eyes, had paracentesis done on the right cornea on account of hypopyon. After nine months the right cornea was entirely opaque, everywhere traversed by blood vessels and showing a thick button of granulation tissue.

Schaeche's case of a boy who developed panophthalmitis with perforation, after mortar injury six months before, also belongs here. Large, mushroom-like granulomas formed at the point of perforation.

The case represented by Pagenstecher and Genth on their Plate 12, Figures 3 and 5, may possibly be classed here.

Lawson's case of a cicatrix horn growing from the cornea, seems to be an unusual form of granulation tissue formation developing after corneal perforation.

2. Of the granulomas belonging in Groups 2 and 3 of the foregoing classifications, the textbooks make no mention whatsoever. The American Encyclopedia of Ophthalmology contains

only meager reference to these conditions on pages 3436 and 5631. A good description by Wintersteiner with enumeration of the cases reported is found in the German Encyclopedia and may be repeated here: "As granulomas of the cornea have been described some few reddish, soft tissue-granulations growing to pea size which later become pedunculated and regressing and which developed after an ulcer, an injury, or a chronic inflammation." No mention of the condition is made in the French Encyclopedia.

The only other references to granuloma of the sclerocorneal type in the available American literature are found when Weeks, discussing granuloma pyogenicum of the lids, wonders whether the so-called granuloma of the cornea or of the sclerocorneal margin is not akin to it. The granuloma of the cornea has a tendency to recur, he says. He has examined two sclerocorneal tumors. In the same discussion, Jackson mentions a case of granuloma at the margin of the cornea, in existence six to eight weeks, having a purplish red surface; the edges reminded one of an epithelioma, but were perfectly soft.

In the discussion of burns of the eyeball by lime, Lewin and Guillery mention the following cases in which the granuloma formation began in the conjunctiva of the eyeball and advanced onto the cornea. (1) The cornea of a mason's helper, after mortar had splashed into his left eye, became covered with granulation tissue, reaching from the limbus almost to the center altho no ulceration had developed. (2) The case of Desmarres of a mason whose cornea after he had fallen into a lime pit became covered with a sarcomatous growth. (3) After getting lime into the right eye twenty-five days before, a boy showed mulberry excresences on the swollen conjunctiva and the vascularized limbus. Two months later, the excrescences covered the whole cornea. After three months, only a small point of the cornea was clear and the remainder was covered by an enormous granulomatous mass pedunculated at the base. (4) Gosart's case of a fleshy pterygium which partially covered the cornea.

In this group also belongs, without doubt, our first case.

Beierle reports a case belonging in this group of hypertrophy of the conjunctiva and granuloma on the otherwise intact cornea of a dog. He assumes injury of the cornea.

3. The most interesting group is formed by those cases in which the granuloma unquestionably originated in the cornea itself, away from the limbus, and did not follow perforation—only resulting from a destruction of corneal tissue, with or without the formation of an ulcer. It is for these cases alone for which the term granuloma of the cornea should be reserved. Search of the available literature discloses only the following cases.

Blaskovics' patient, a woman, aged 25, had recurrent eye inflammation with photophobia when a child. When 8 years old, she received an injury to the right eye and a white spot in the center of the cornea resulted from it. Four years before she came under observation, a red area appeared in the center of the spot and increased gradually. When seen by Blaskovics, the tumor was 10 by 11 mm. in diameter, 1 mm. thick, yellowish red and soft, its surface irregular. Granuloma from an iris prolapse was considered a possibility, but tumor of the cornea finally diagnosed. The examination of the enucleated eye revealed no bacteria. The cornea showed absence of the superficial layers in the center. The deeper layers were loosened. Near the growth the cornea was infiltrated with round cells and numerous vessels extended into it from the conjunctiva. Bowman's membrane was absent in the whole extent of the growth. A 1 mm. band of unaffected cornea extended all around the growth. It was divided by connective tissue septums, forming wide meshes. These contained homogeneous intercellular substance with small round cells, and the nuclei were often in mitosis. He considers it a case of typical granuloma of the cornea.

Blaskovics also quotes as true granu-

loma the three cases of Bock. In his first publication, Bock relates two cases of granuloma formation of the cornea among ninety-two cases of parenchymatous keratitis. The masses disappeared gradually and left dense opacities. His third case was that of a boy, aged 13, who had had parenchymatous keratitis of the right eye some time before and on whose left eye a growth developed during the four weeks previous to consultation. In the center of the opaque cornea, which showed deep vessels, a growth of 3 mm. was visible. It increased rapidly during the two weeks of observation and became constricted at the base. The excised growth showed the picture of a wound granuloma. Its pedicle was covered with one layer of epithelium. The condition is looked upon as the result of a circumscribed excessive accumulation of lymphoid cells which after breaking thru the lamellae in front of it, could grow unhindered. These cases are not mentioned in Lagrange's excellent work.

The case of Pagenstecher and Genth on their Plate 12, Figures 1 and 2, is an undoubted case of pure granuloma of the cornea proper, tho some misunderstanding has been created in the literature about it, owing to the use of the word sarcoma in the English translation of the German text. Its granulomatous character is also maintained by Lagrange and by Gayet, whom he quotes.

The granuloma in Raabe's case developed at the seat of a healing septic ulcer of the cornea which had been cauterized. The histologic examination showed granulation tissue.

Hirschberg and Ginsberg describe a large, prominent, coxcomb-like, grayish-red granulomatous tumor on the cornea of a girl of 9 having tuberculosis. The tumor showed granulation tissue with numerous leukocytes and areas of myxomatous tissue. It was not covered by epithelium.

A vascular pedunculated growth, developing rapidly after injury, was reported by Bargeton and thought to be possibly a sarcoma, but histologic examination confirmed the clinical diagnosis of botryomycosis. A similar diagnosis was made by Reihaus whose patient, a woman of 46, had much eye inflammation when a child, and whose left cornea showed a small white tumor beginning at the lower margin and extending into the pupillary area. The histologic examination of the excised tumor revealed it possibly to be the product of proliferating inflammation and certain small bodies found are interpreted as "hefa." Axenfeld, reviewing these two cases, says, "There is no proof that any of the cases were any different from what have been described in the literature as granulomas. Further investigation is necessary to determine the pathogenesis of these growths."

Our Case 2 agrees in all histologic essentials with the cases of Blaskovics, Bock, Pagenstecher and Genth, Raabe, Hirschberg and Ginsberg, etc., and is therefore, one of a pure granuloma of the cornea, of which histologic examination could be made.

Bajardi reports a pedunculated granuloma on the cornea of a rabbit, probably resulting from an ulcer. It was covered with epithelium. Gay found a pea-sized tumor on the cornea of a bitch, consisting of a granulation tissue.

It does not seem quite certain that the case of Adler is really a case of granulomas of the cornea although apparently classed as such by Lagrange. Strangely enough, this case does not seem to be reviewed in the contemporaneous German literature. A railroad employee, suffering from gradual diminution of sight with moderate local inflammation of the eyes for two years, showed gray, gelatinous granulations on each cornea, eighteen on the left and fewer on the right eye. The histologic examination revealed them to be a kind of miliary granuloma, consisting of corneal tissue covered by an epithelium much thicker than normal and suggesting those fibrous formations one sees especially on serous membranes following chronic inflammation. But in view of the peculiar histologic findings the bilateral arrangement. the multiplicity of the growths.

and finally because of the occupation of the patient it might be pardonable to think that the condition of each cornea was nothing else but a kind of hypertrophy of the corneal epithelium, as seen at times after recurring irritation, produced in this case by repeated foreign body injuries.

A number of cases are recorded in the literature under different names, such as fibroma, myxoma, sarcoma, etc., in which the condition described can without undue force be explained as some result of granuloma formation of the cornea either showing greater development of fibrous tissue, or showing changes of a myxomatous nature, etc. Some of them are undoubtedly only changes in a pseudocornea following perforation or destruction of the cornea. As such may be classed the cases of H. Adler, Benson Cases 1 and 2, Capellini, Falchi, Gallenga, Mitvalsky, Polignani, Qualino and Guaita, Rogman, Rumschewitsch, cases 1 and 2, Scott and Story, Silex, Simon, Szokalski, Zirm, etc. In this connection Parsons (264, 265) remarks: "No sharp line can be drawn between purely inflammatory conditions and many so-called growths . . . As to the embryonic spindle-celled type of sarcoma, it may be doubted whether some of them are not simple granulomata (granulation tissue)." Similar opinions are voiced by Lagrange, Blaskovics and Wintersteiner.

It is difficult to say where Stellwag's case is to be placed. The histologic examination, tho quite insufficient for classification, is not of such a character as to exclude the possibility of a granulomatous origin.

ETIOLOGY.
